CHAPTER 66

PATHOBIOLOGY OF ACUTE LYMPHOBLASTIC LEUKEMIA

Melissa A. Burns, Alejandro Gutierrez, and Lewis B. Silverman

INTRODUCTION

Normal lymphoid precursors undergo somatic recombination at their immunoglobulin (Ig) or T-cell receptor (TCR) gene loci, and the successful completion of V(D)J recombination, with the resultant formation of a functional Ig or TCR, is required for the survival of lymphocyte precursors. Positive and negative selection steps ensure that only lymphocytes with Ig or TCRs that function appropriately within the context of an individual's immune microenvironment are allowed to proceed through the proliferation and differentiation steps required for the development of mature lymphocytes. This developmental process generates a repertoire of mature lymphocytes with unique variations in the antigen-recognition portions of the Ig or TCR genes; together, these form the foundation of the adaptive immune system that can recognize a countless variety of foreign antigens. The acquisition of mutations of oncogenes or tumor suppressors during this developmental process, which can be mediated by the off-target activity of the V(D)J recombination machinery, can generate lymphocyte clones with uncontrolled proliferation and differentiation arrest, features characteristic of acute lymphoblastic leukemia (ALL). Many of these genetic alterations have prognostic significance and are used in contemporary ALL treatment protocols to adjust the intensity of therapy. Although the incidence of specific genetic alterations in ALL varies according to patient age and immunophenotype (Fig. 66.1), evidence suggests that the pathogenesis underlying malignant transformation in molecularly defined subsets of ALL is similar across age groups.

LINEAGE-SPECIFIC FEATURES OF LEUKEMIC LYMPHOBLASTS

Malignant lymphoblasts share many of the features of normal lymphoid progenitors. Thus, ALL cells rearrange their Ig and TCR genes and express components of antigen receptor molecules and other differentiation-linked cell-surface glycoproteins in ways that correspond to features of developing normal B and T lymphocytes. In some cases, leukemic cells appear to represent the clonal expansion of a lymphoid progenitor that has arrested its development at an early stage of B- or T-cell differentiation, while in others, the blast cell phenotypes differ from those of normal lymphocyte progenitors, which is likely a result of aberrant regulation of gene expression. Still, the general concept that leukemic cells should be classified according to their "normal" developmental stage remains an important one, providing a basis for the study of immunophenotype-specific genetic changes.

Mature B-Cell Acute Lymphoblastic Leukemia

The diagnosis of mature B-cell ALL, also termed Burkitt leukemia, is based on the detection of surface Ig on leukemic blasts. This rare phenotype accounts for only 2% to 3% of ALL cases, and the lymphoblasts often have distinctive morphology, with deeply basophilic cytoplasm containing prominent vacuoles; this morphologic pattern was designated L3 in the French-American-British (FAB) system. Mature B-cell ALL is a disseminated form of Burkitt lymphoma, as these conditions share common cytogenetic, molecular, phenotypic, and clinical features. Mature B-cell ALL does not respond well to chemotherapy traditionally used for childhood ALL. However, favorable outcomes have been obtained with treatments designed for Burkitt lymphoma, which involves therapy of greater intensity and shorter duration. Thus, mature B-cell leukemia was the first subtype of ALL to be recognized as a distinct clinical entity based on immunophenotypic and cytogenetic features and the first to be treated by separate protocols designed specifically for the leukemia's unique features.

B-Cell Acute Lymphoblastic Leukemia

Approximately 80% of ALL patients have lymphoblasts with phenotypes corresponding to those of B-cell progenitors. These cases can be identified on the basis of cell-surface expression of CD19 and at least one other recognized B lineage–associated antigen: CD20, CD24, CD22, CD21, or CD79. The most common subtype of B-cell ALL, previously termed common precursor B-cell ALL, also expresses CD10. These lymphoblasts may also express nuclear terminal deoxynucleotidyl transferase (TdT) or CD34. About one-fourth of B-cell ALL cases express cytoplasmic Ig μ heavy-chain proteins and were historically designated pre-B-ALL.

DNA rearrangement of Ig genes occurs before heavy-chain gene expression in B-cell development, providing a genetic marker of B-lymphocyte ontogeny. Korsmeyer and colleagues pioneered the use of heavy- and light-chain gene rearrangements to support an early B-lineage origin of most ALL blasts. However, Ig heavy-chain gene rearrangements are observed in about 15% of T-cell ALL cases and in a similar percentage of AML cases. Thus, caution must be exercised when assigning cell lineage on the basis of studies of Ig gene rearrangement.

The identification of specific immunophenotypic, genetic, and clinical features that predict response to therapy in patients with B-lineage ALL and the use of these predictors to stratify intensity of therapy are now common features of contemporary ALL treatment protocols. This ability to predict outcome has been closely tied to the remarkable improvements in therapy for children with this disease, which 60 years ago was universally fatal. However, many subgroups of pediatric and adult patients continue to face a poor prognosis, and much progress remains to be made.

T-Cell Acute Lymphoblastic Leukemia

Lymphoblasts with a T-cell phenotype, defined by the WHO as cell-surface expression of TdT with variable expression of CD1a, CD2, CD3, CD4, CD5, CD7, and CD8, comprise approximately 15% of cases of childhood ALL and a higher proportion of ALL in adults. These cases can be further classified according to the sequence of expression of T-cell-associated surface antigens during normal thymocyte ontogeny. Numerous investigators, using a battery of monoclonal antibodies specific for T-cell surface glycoproteins, have confirmed the close relationship between the recognizable patterns of surface antigen expression on leukemic T cells and the normal stages of thymocyte development. T-cell ALL is often associated with distinctive clinical features that include high circulating leukocyte counts, male predominance, central nervous system involvement, and a radiographically evident thymic mass in many

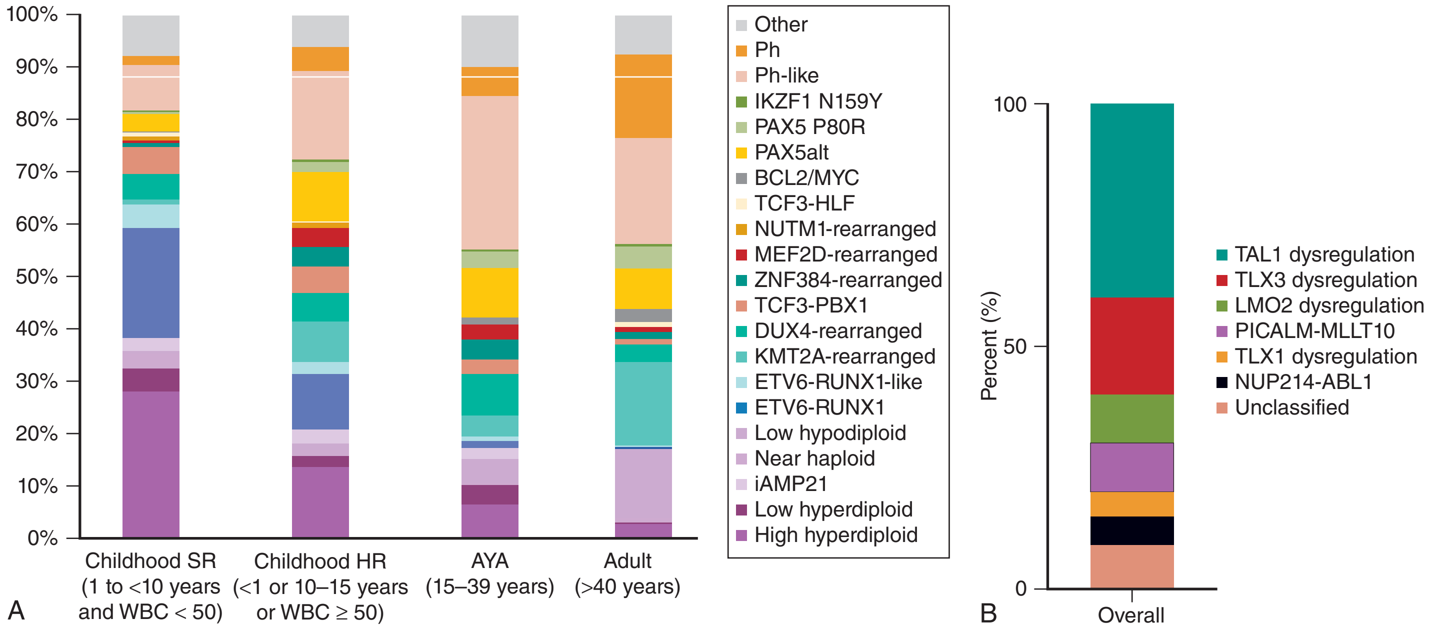

Figure 66.1 FREQUENCY OF THE MAJOR MOLECULAR CLASSIFICATIONS IN (A) PEDIATRIC AND ADULT B-CELL AND (B) PEDIATRIC T-CELL ACUTE LYMPHOBLASTIC LEUKEMIA (ALL). *(A, Adapted from Inaba H, Mullighan CG. Pediatric acute lymphoblastic leukemia. Haematologica. 2020;105:11 [Fig. 2], with permission; B, From Williams LA, Yang JJ, Hirsch BA. Is there etiologic heterogeneity between subtypes of childhood acute lymphoblastic leukemia? A review of variation in risk by subtype. Cancer Epidemiol Biomarkers Prev. 2019;28:846–856 [Fig. 1].)*

cases at presentation. Historically, patients with T-cell ALL had an adverse prognosis compared with patients with B-cell ALL; however, with contemporary therapy, outcomes are similar. In marked contrast to B-cell ALL, in which the availability of a wide range of clinical and genetic prognostic markers has allowed the development of treatment protocols tailored to an individual patient's risk of relapse, robust pretreatment prognostic markers are lacking in T-cell ALL. Recent discovery of biomarkers of differentiation arrest at the earliest stages of T-cell development has identified potential markers of treatment resistance.

A distinctive subset of T-cell ALL has been identified that is associated with an increased risk of slow early response and/or early treatment failure, the so-called early T-cell precursor (ETP) subset of T-cell ALL. ETP ALL comprises 8% to 15% of pediatric T-ALL cases but accounts for a much higher fraction of T-cell ALL in adults and is characterized by differentiation arrest at the earliest identifiable stages of T-cell development. These cases are most commonly identified by a specific immunophenotype, which can be defined by the lack of expression of the T-lineage cell-surface markers CD1a and CD8, weak or absent expression of CD5, and aberrant expression of one or more myeloid or stem cell markers. ETP cases also express a distinctive gene expression profile and often have an absence of biallelic TCRγ deletion (ABD), indicating differentiation arrest prior to the completion of TCR gene rearrangement. In addition to harboring oncogenic lesions typical of T-cell ALL, ETP cases also harbor gene mutations that are characteristic of acute myeloid leukemia, including mutations of Polycomb repressive complex 2 (*PRC2*) genes (*EZH2, EED,* or *SUZ12*) and *WT1* mutations, suggesting that the cell of origin of ETP leukemia may be a multipotent hematopoietic stem or progenitor cell rather than a committed T-cell progenitor. Evidence also indicates that a subset of AML cases have features characteristic of T-cell differentiation, suggesting that current WHO classification schemes may have resulted in the separation of a biologically unique entity with features of both T-lymphoblastic and myeloid differentiation across the T-cell ALL, AML, and mixed-phenotype acute leukemia (MPAL) diagnostic categories. The term acute myeloid/T-lymphoblastic leukemia has been proposed for this entity, although defining the optimal therapeutic approach for these cases requires additional investigation.

Mixed-Phenotype Acute Leukemia

MPAL defines a heterogenous class of leukemias in which blast cells coexpress antigens of both lymphoid and myeloid lineage. Historically, two distinct forms of these leukemias have been recognized: biphenotypic leukemia, which accounts for the majority of MPAL and can be the result of cells coexpressing B-cell or T-cell antigens together with myeloid-associated antigen (B/myeloid MPAL and T/myeloid MPAL, respectively), or more rarely cells that coexpress B-cell and T-cell antigens (B/T MPAL) or B-cell, T-cell, and myeloid antigens (B/T/myeloid MPAL), and bilineal leukemia, in which there are two distinct populations of cells (generally one lymphoid and one myeloid). Despite recent work investing the complex genomic and epigenomic landscape of MPAL, the origin of this subtype remains unknown. One possibility is the malignant transformation of pluripotent hematopoietic stem or progenitor cells that retain the ability to differentiate in both the myeloid and lymphoid lineages; another is the immortalization of rare progenitor cells that normally coexpress features of both lineages; and a third is aberrant gene expression caused by specific genetic alterations. Despite initial controversy, co-expression of myeloid antigens in ALL, or of lymphoid markers in acute myeloid leukemia, does not appear to have prognostic significance in the setting of contemporary treatment regimens.

GENETIC BASIS OF ACUTE LYMPHOBLASTIC LEUKEMIA

Genome-wide profiling studies, including whole-genome sequencing, transcriptome sequencing, and microarray analyses, have led to major advances in understanding the genetics of ALL through the identification of recurrently mutated cellular pathways, much of which has been shown to have direct clinical relevance. While an in-depth analysis of the genetics of ALL is beyond the scope of this chapter, we present here an overview of select genetic lesions that have provided key insights into mechanisms of leukemogenesis. Mutations are classified based on their predominant cellular consequence, which is an imperfect and simplified classification scheme because some mutations can induce more than one type of cellular aberration. Nevertheless, we believe this provides a useful conceptual framework for understanding the molecular pathogenesis of ALL.

Aberrant Activation of Oncogenic Transcriptional Programs

Dysregulated activation of oncogenic transcriptional programs is a central theme in the pathogenesis of ALL. Many of the proto-oncogenes recurrently activated by genetic lesions are transcription factors that regulate proliferation and differentiation during the development of various embryonic tissues. Thus, co-option of normal developmental pathways plays a central role in human leukemogenesis. Transcription factors are commonly activated by chromosomal translocations in ALL, but the consequences of translocations tend to vary according to the ALL subtype. In mature B-cell ALL and in T-cell ALL, these genetic lesions often lead to the aberrant expression of structurally intact genes. By contrast, the chromosomal translocations that often occur in B-cell ALL generally lead to the expression of chimeric fusion proteins.

Activation of Structurally Intact Transcription Factors

MYC in Mature B-Cell Acute Lymphoblastic Leukemia

The vast majority of cases of mature B-cell ALL (Burkitt leukemia) are characterized by a translocation that places one allele of MYC from chromosome 8 under the control of the regulatory elements of an *Ig* gene, either the heavy-chain gene on chromosome 14q32 or the κ or λ light-chain genes on chromosomes 2 and 22, respectively. These translocations are oncogenic because they result in lineage-specific overexpression of MYC, a prototypical basic helix–loop–helix oncogenic transcription factor. The mechanisms through which MYC exerts its potent oncogenic effects have been the subject of intense investigation. MYC has been estimated to regulate the expression of 15% of the genome and leads to the transcriptional activation of a large number of genes involved in cell division, growth, metabolism, adhesion, and motility. MYC also exerts post-transcriptional effects on gene expression by regulating microRNA expression and ribosome biogenesis. MYC exerts its transcriptional activity via the formation of heterodimers with its DNA-binding partner protein MAX. MYC–MAX heterodimers bind to canonical hexameric E-box DNA sequences (5′-CACGTG-3′) where they activate transcription. MAX can also heterodimerize with other bHLH proteins, including MAD, MXI-1 (MAD2), and MNT. Whereas transcriptional activation by MYC–MAX complexes promotes proliferation, binding by MAD–MAX and other MAX heterodimers produces opposite effects. For example, MAD inhibits MYC function both by competing with MYC for binding to MAX and by directly inhibiting transcription.

Recent work has revealed that a major consequence of MYC overexpression is the global amplification of gene expression. Investigation of transcriptional regulation mechanisms has revealed two distinct steps in the regulation of gene expression by transcription factors. First, RNA polymerase II and its associated transcriptional apparatus are loaded onto a gene promoter by one set of transcription factors, but RNA polymerase is often initially “paused” near the proximal promoter. Subsequent release from transcriptional pause is a distinct and highly regulated step in the control of gene expression. Unexpectedly, recent studies have revealed that a major consequence of MYC overexpression is the release of transcriptional pause at genes that were already loaded with RNA polymerase, rather than the recruitment of RNA polymerase to new target genes. These findings support a model in which MYC overexpression functions to amplify the expression of genes that are already being transcribed, thus “locking in” a cell’s existing transcriptional program. The acquisition of an MYC-activating lesion in a cell with a highly proliferative gene expression program that is normally transient, such as an immature B-cell progenitor, can lock this cell in this highly proliferative state, thus providing one mechanism to explain MYC-driven oncogenesis.

TAL1 and LMO Genes in T-Cell Acute Lymphoblastic Leukemia

In leukemia with a T-cell phenotype, the breakpoints of recurrent chromosomal translocations consistently juxtapose *TCR* gene-regulatory elements, which are highly active in committed T-cell progenitors, to the protein-coding sequence of oncogenic transcription factors, which then become aberrantly overexpressed as a result of these translocations. The best characterized of the oncogenic transcription factors involved is TAL1 (also known as SCL). TAL1 is overexpressed as a result of the recurrent t(1;14) translocation or intra-chromosomal deletions in approximately one-fourth of childhood T-cell ALL cases. However, TAL1 is aberrantly expressed in the leukemic cells of 60% of children and 45% of adults with T-cell ALL, implicating additional pathogenic mechanisms leading to TAL1 overexpression. One such recently described mechanism is an activating mutation of a noncoding gene-regulatory element, which is described later in this chapter. TAL1 acts as a master regulatory protein during early hematopoietic development and is required for the generation of all blood cell lineages. However, it does not seem to be required for the generation and function of hematopoietic stem cells (HSCs) during adult hematopoiesis. *TAL1* is a bona fide T-cell ALL oncogene, as its aberrant expression in murine T-cell progenitors induces T-cell ALL.

TAL1 binds DNA in complex with other transcription factors including TCF3 (also known as E2A), HEB, LMO1/2, GATA3, RUNX1, and MYB. TAL1 binding can activate or repress the expression of its target genes, and a number of these targets have been implicated in T-cell transformation. In murine T-cell progenitors, TAL1 expression inhibits TCF3 transcriptional activity, and loss of TCF3 function induces T-cell leukemias in mice, supporting a role for TAL1-mediated inhibition of TCF3 function in leukemogenesis. The TAL1 complex binds and upregulates the expression of several of its own core components, including TAL1, GATA3, RUNX1, and MYB, thus forming a positive feedback loop that reinforces the activity of this oncogenic transcriptional complex. TAL1 also upregulates the expression of *TRIB2*, a gene whose overexpression in mouse bone marrow cells induces myeloid leukemia and whose expression is required for the survival of *TAL1*-overexpressing T-cell ALL. Furthermore, TAL1 also upregulates the expression of the microRNA mir223, which promotes leukemic cell survival by downregulating the expression of the *FBXW7* tumor suppressor.

The LIM-only domain genes, *LMO1* and *LMO2*, are also involved in recurrent chromosomal translocations in T-cell ALL. These genes encode transcription factors that interact with TAL1 in erythroid cells and in T-cell leukemias. Homozygous disruption of *LMO2* in mice phenocopies the hematopoietic defect of *TAL1* knock-outs, suggesting that these proteins function together during hematopoietic development. In addition, overexpression of *LMO1* and *LMO2* in murine thymocytes leads to T-cell transformation and accelerates the onset of leukemias in *TAL1* transgenic mice.

Homeobox Genes

The homeobox gene *TLX1* (also known as *HOX11*) is the founding member of a family of homeobox genes that includes *TLX2 (HOX11L1)* and *TLX3 (HOX11L2)*, each of which plays key roles in embryonic development. *TLX1* was originally isolated from the recurrent t(10;14) translocation in T-cell ALL and is aberrantly expressed in 5% of pediatric and approximately 25% of adult T-cell ALL cases. *TLX3* is also involved in a recurrent t(5;14)(q35;q32) translocation and is overexpressed in approximately 25% of pediatric but in only 5% of adult T-cell ALL. *TLX1* and *TLX3* encode very similar proteins, suggesting they have similar oncogenic mechanisms. Overexpression of *TLX1* or *TLX3* induces differentiation arrest at a cortical stage of T-cell development, an effect that is mediated by TLX-induced transcriptional repression of the pre-TCR alpha, whose expression is required for progression beyond this stage in normal T-cell development. *TLX1* expression in murine T-cell progenitors induces T-cell ALL, and these tumor cells have a defective mitotic checkpoint due to transcriptional repression of the checkpoint kinase *CHEK1*. These findings, together with the previous observation that TLX1 binds the catalytic subunits of the phosphatases PP2A and PP1 and disrupts the G2/M checkpoint, thus provide a mechanistic explanation for the association of *TLX1*/*TLX3* overexpression with aneuploidy, which is otherwise rare in human T-cell ALL. RUNX1, which is directly bound and repressed by TLX1 and TLX3, has been implicated as a downstream mediator of the oncogenic function of these transcription factors in T-cell ALL.

The cluster of *HOXA* genes on chromosome 7 is affected by a recurrent chromosomal inversion that places it in the vicinity of *TCR* beta gene-regulatory elements, leading to aberrant expression of the entire *HOXA* cluster in approximately 5% of cases of T-cell ALL. Many of these cases also carry cooperating oncogenic lesions consisting of *NOTCH1* gene mutations and deletions of 9p21. This translocation provides additional evidence for the role of aberrant *HOXA* activation in leukemogenesis and in the pathogenesis of *KMT2A*- and *CALM-AF10*-rearranged leukemias, as reviewed in more detail in the following sections.

DUX4 Gene Rearrangements in B-Cell Acute Lymphoblastic Leukemia

The double homeobox 4 (*DUX4*) gene encodes a homeobox-containing protein and is located on chromosome 4q within a sub-telomeric D4Z4 repeat region. In normal lymphoid cells, *DUX4* undergoes epigenetic silencing. Recent genomic studies, however, have identified recurrent gene rearrangements in approximately four percent of B-cell ALL cases that fuse *DUX4* to either *IGH* or, less commonly, *ERG*, a member of the erythroblast transformation-specific (ETS) family of transcription factors and an important regulator of hematopoietic cells. The juxtaposition of *DUX4* to the regulatory region of *IGH* or *ERG* results in *DUX4* overexpression in lymphoblasts. This overexpression leads to deregulation of *ERG* through binding of DUX4 to an alternative transcription initiation site within intron 6 of ERG, leading to truncated form of *ERG* that lacks the N-terminal pointed domain and central regulatory domains, but retains the DNA-binding ETS and transactivation domains, called ERGalt. Mice transplanted with ERGalt develop lymphoid malignancies, suggesting that expression of ERGalt directly induces lymphoid leukemogenesis. *DUX4* gene rearrangements commonly co-occur with *ERG* deletions in B-cell ALL, suggesting that *ERG* deletions are secondary cooperating events in this subtype of B-cell ALL. Interestingly, *IKZF1* deletions are commonly found in *DUX4*/*ERG* mutated B-cell ALL; however, unlike other ALL subtypes, *IKZF1* deletions are not associated with a poor outcome in this group of patients.

Chimeric Transcription Factor Oncogenes

Chromosomal translocations resulting in the formation of chimeric proteins represent a second mechanism for aberrant transcription factor activation, which is more prevalent in B-cell ALL. These translocations juxtapose exons that encode the DNA-binding and protein-binding domains of different genes, resulting in the expression of a chimeric fusion protein. The generation of such fusions is facilitated by the modular structure of transcription factor genes, in which discrete exons encode particular functional domains. This feature of gene structure facilitates organismal evolution but is commonly co-opted during oncogenesis.

ETV6-RUNX1 Fusions in B-Cell Acute Lymphoblastic Leukemia

Although most t(12;21) translocations are not detectable by standard cytogenetic analysis, this translocation is detectable by molecular techniques in approximately 25% of childhood B-cell ALL, making this the most common translocation in pediatric ALL (see Fig. 66.1). The *ETV6–RUNX1* translocation often arises prenatally and is likely to be the initiating mutation in at least a subset of ALL, as evidenced by the identification of identical *ETV6–RUNX1* translocations in identical twins with concordant ALL, and in retrospectively analyzed neonatal blood specimens of children who were diagnosed with ALL many years later. However, *ETV6–RUNX1* alone is not sufficient for leukemogenesis because the incidence of detectable *ETV6–RUNX1* fusions in the blood of normal newborns is about 100-fold greater than the incidence of leukemia.

The molecular mechanisms mediating *ETV6–RUNX1* induced leukemogenesis remain poorly understood. This fusion gene encodes a chimeric protein that contains the helix–loop–helix (HLH) domain of *ETV6* fused to nearly all of *RUNX1* (also known as *AML1* or *CBFA2*), including both the transactivation domain and the DNA- and protein-binding Runt homology domain. Both of these genes are found in other leukemia-related translocations, and both are essential for normal hematopoiesis. *ETV6* was first identified in the t(5;12) in chronic myelomonocytic leukemia, where it is fused to the platelet-derived growth factor receptor gene (*PDGFRB*), and is also fused to *ABL, MN1,* and *EVI1* in AML and to *JAK2* in T-cell ALL. *ETV6* is required for fetal hematopoiesis in the mouse. Interestingly, the inactivation of *ETV6* in adult mice leads to the selective loss of HSCs from adult bone marrow, but hematopoiesis is sustained by committed precursors. Many *ETV6–RUNX1* leukemias show the loss of the normal *ETV6* allele, suggesting that the leukemogenic effect of *ETV6-RUNX1* may be mediated in part by the loss of wildtype (WT) *ETV6* function. Interestingly, germline loss-of-function *ETV6* mutations have been identified in patients with familial thrombocytopenia and a predisposition to hematologic malignancies including ALL (as described in further detail later in this chapter), further implicating WT *ETV6* as an ALL tumor suppressor.

RUNX1 is the DNA-binding component of the *RUNX1–CBFß* transcription factor complex disrupted by the t(8;21), t(3;21), and inv(16) in AML. RUNX1 is a transcription factor that is required for the expression of several hematopoietic genes involved in myeloid and lymphoid development, including *PU.1* and *IL-3*, although it can also act as a transcriptional repressor in some settings. Homozygous disruption of the murine *RUNX1* or *CBFB* genes results in the lack of definitive hematopoiesis, indicating that genes regulated by *RUNX1* are essential for normal hematopoietic development. Additionally, rare familial mutations in the *RUNX1* DNA-binding domain lead to the familial platelet disorder and predisposition to both myeloid and lymphoid malignancies.

The presence of the *ETV6–RUNX1* translocation is associated with a favorable prognosis, with long-term event-free survival rates of approximately 90% in a number of studies.

TCF3-PBX1 Fusion Genes in B-Cell Acute Lymphoblastic Leukemia

Another example of an oncogenic chimeric transcription factor is the TCF3-PBX1 (previously known as E2A-PBX1) rearrangement, which results from the t(1;19)(q23;p13) chromosomal translocation present in about 5% of all B-lineage ALLs and in 25% of cases with a pre-B (cytoplasmic Ig-positive) phenotype. This translocation fuses the two N-terminal transactivation domains of the *TCF3* transcription factor on chromosome 19 to the DNA-binding domain of the homeobox gene *PBX1*, leading to the expression of hybrid TCF3-*PBX1* oncoproteins. The transforming potential of TCF3–PBX1 was first demonstrated by the rapid induction of AML in lethally irradiated mice repopulated with hematopoietic progenitors transduced with *TCF3–PBX1* genes. This fusion has also been shown to transform NIH-3T3 fibroblasts and induce T-cell lymphomas in transgenic mice. Additional studies have shown that deletion of one of the *TCF3* activation domains diminishes its transforming activity, but deletion of the *PBX1* homeodomain has no effect. Historically, the presence of the *TCF3–PBX1* translocation was associated with an inferior prognosis, but this no longer is the case with contemporary protocols for childhood ALL.

TCF3–HLF Fusion Genes in B-Cell Acute Lymphoblastic Leukemia

The t(17;19) is a rare recurrent chromosomal translocation that fuses the amino-terminal transactivation domains of *TCF3* to the C-terminal DNA binding and dimerization domains of *HLF*, a basic leucine zipper domain transcription factor. Although TCF3–HLF can bind DNA either as a homodimer or as a heterodimer with HLF and related proteins, no other PAR proteins are expressed in hematopoietic cells, and the TCF3–HLF fusion binds DNA as a homodimer in cells harboring the t(17;19). Similar to TCF3–PBX1, TCF3–HLF can transform NIH–3T3 fibroblasts, a process that requires the *HLF* leucine zipper domain and the *TCF3* transactivation domains, and can induce lymphoid tumors in transgenic mice. Recent transcriptomic analysis has revealed that the *TCF3–HLF* fusion leads to a gene expression signature enriched for stem cell and myeloid markers, suggesting that this fusion leads to cellular reprogramming of a lymphoid progenitor to a more primitive state. Additionally, another major consequence of TCF3–HLF expression in lymphoid precursors is the inhibition of apoptotic cell death. In normal pro-B lymphocytes, the expression of TCF3–HLF blocks apoptosis induction by either IL-3 or p53. In TCF3-HLF expressing human ALL cells, the inhibition of TCF3–HLF function by expression of a dominant-negative form of TCF3–HLF results in apoptosis induction. HLF is the mammalian homolog of the worm protein ces-2, a transcription factor that is necessary for the death of two specific nerve cells during *Caenorhabditis elegans* development. This pathway, which is evolutionarily conserved, is inhibited by the TCF3-HLF fusion. Thus, in contrast to the proapoptotic role of the WT HLF homolog (ces-2) in worms, TCF3–HLF blocks apoptosis by inducing the expression of SLUG, a transcription factor that blocks DNA damage-induced apoptosis in hematopoietic cells. The t(17;19) occurs in less than 1% of ALL cases, is associated with characteristic clinical features including adolescent age, disseminated intravascular coagulation and hypercalcemia at diagnosis, as well as a high risk of treatment failure leading to a dismal prognosis.

MEF2D Gene Fusions in B-Cell Acute Lymphoblastic Leukemia

Cryptic fusions involving *MEF2D* at chromosome 1q21–22 have recently been identified through RNA sequencing studies. *MEF2D*, located at chromosome 1q21–22, encodes myocyte enhancer factor 2D and is a member of the myocyte enhancer factor family of transcription factors that are expressed throughout normal B-cell development. Previous studies have shown that the inactivation of *MEF2D* Results in maturation arrest at the pre-B-cell stage of lymphoid development. In these cases, the amino terminus of *MEF2D* fuses in frame with the carboxy terminus of the fusion partner. Several fusion partners of *MEF2D* have been identified, including most commonly *BCL9*, which is a component of the *WNT*/β-catenin signaling cascade. The prognostic implication of *MEF2D* gene fusions has not yet been established.

ZNF384 Gene Fusions in B-Cell Acute Lymphoblastic Leukemia

Fusions involving the zinc-finger protein 384 (*ZNF384*) gene, which encodes a transcription factor that regulates promoters of the extracellular matrix, have recently been identified through RNA sequencing and transcriptomic analyses in B-cell ALL. To date, eight fusion partners have been identified, including *BMP2K, TCF3, TAF15, EWSR, EP300, CREBBP, SYNRG,* and *ARID1B. ZNF384*-related fusion genes have demonstrated the transformation of NIH3T3 fibroblasts in vitro; however, their exact cellular consequences and role in leukemogenesis remain unknown. B-cell ALL cases that harbor *ZNF384*-related fusions are characterized by a unique immunophenotype that is weak or negative for CD10 and positive for the myeloid markers, CD13 and CD33, but are variable in clinical presentation. *ZNF384* gene fusions have also been observed in up to 50% of B-cell/myeloid cases of MPAL.

CALM–AF10 Fusion Gene in T-Cell Acute Lymphoblastic Leukemia

The t(10;11)(p13;q14) is detected in approximately 3% to 10% of T-cell ALL cases and in occasional AML cases. This translocation results in the fusion of *CALM* (also known as *PICALM*), encoding a protein with high homology to the murine clathrin assembly protein ap3, with *AF10*, a gene identified as a *KMT2A* partner in the *KMT2A–AF10* fusion resulting from the t(10;11)(p13;q23). The expression of the *CALM-AF10* fusion transcript has been associated with early arrest in T-cell development and with differentiation into the gamma-delta lineage in T-cell ALL. Additionally, aberrant upregulation of *HOX* gene expression appears to be involved in *CALM–AF10*-mediated leukemogenesis, at least in acute myeloid leukemia cells that carry this translocation. Interestingly, analysis of a mouse model of *CALM–AF10*-induced acute myeloid leukemia suggests that the leukemic stem cell in this model has lymphoid characteristics, and cells from human patients with AML can be identified that have similar characteristics to the disease-propagating cell in this animal model.

SPI1 Fusion Genes in T-Cell Acute Lymphoblastic Leukemia

Sequencing studies pf pediatric T-cell ALL have recently identified recurrent *SPI1* fusions (*STMN1-SPI1* and *TCF7-SPI1*) in approximately 4% of cases and are associated with poor outcome. *SPI1* is a member of the ETS family of transcription factors and is expressed in hematopoietic cells, where its tight regulation is critical for normal HSC development. During normal T-cell development, *SPI1* is expressed in prethymic and early T-cell progenitors and turned off during later stages of T-cell development. The fusion places SPI1 under the control of *TCF7* or *STMN1* promoter and results in the overexpression of *SPI1*, regardless of fusion partner. In vitro studies demonstrate that expression of *SPI1* fusion genes results in cell proliferation and differentiation arrest during the double-negative (DN) stage of T-cell development, thereby likely contributing to T-cell leukemogenesis.

Activating Point Mutations of Oncogenic Transcription Factors

NOTCH1 in T-Cell Acute Lymphoblastic Leukemia

The *NOTCH1* gene was originally discovered as a partner gene in an exceedingly rare t(7;9) chromosomal translocation in T-cell ALL, in which *NOTCH1* is truncated and placed under the control of the *TCRβ* locus. Despite the rarity of *NOTCH1* translocations, a search for point mutations within the *NOTCH1* gene revealed activating mutations in more than 50% of cases of T-cell ALL. *NOTCH1* plays several critical roles during T-cell development, and its overexpression in murine hematopoietic cells potently drives T-cell ALL. NOTCH1 is a transmembrane protein that is proteolytically processed during its transit to the cell surface, where it exists as a heterodimer consisting of extracellular and transmembrane subunits. Upon ligand binding, the transmembrane subunit undergoes additional proteolytic cleavage within the plasma membrane, leading to the release of its intracellular domain, known as ICN1 (intracellular domain of NOTCH1), into the cytosol. ICN1 subsequently translocates into the nucleus, where it is active as a transcription factor. Activating *NOTCH1* mutations in T-cell ALL can occur as either missense mutations in the heterodimerization domain, allowing constitutive proteolytic activation of the ICN1 domain, or as frameshift or stop codon mutations that lead to truncation of the PEST domain. The PEST domain regulates proteasomal degradation of the protein, and these PEST-inactivating mutations result in aberrant stabilization of ICN1 protein. Mutations in both regions are often found on the same allele in cases of T-cell ALL and are synergistic in increasing NOTCH1 transcriptional output. Additionally, the NOTCH1 oncoprotein can also be stabilized by inactivating mutations of tumor suppressor genes involved in its proteasomal degradation, including *FBXW7* and Cyclin C, as discussed later in this chapter. *MYC* is an important transcriptional target of NOTCH1, and it mediates many of the leukemogenic properties of NOTCH1 in human T-cell ALL cells. However, NOTCH1 also has MYC-independent oncogenic activity, as evidenced by its ability to induce T-cell ALL in zebrafish, where NOTCH1 does not upregulate *MYC* expression. Additional NOTCH1 targets implicated in T-cell ALL pathogenesis include the *IL7R* interleukin receptor and the long noncoding RNA *LUNAR1*, which is upregulated by NOTCH1 and functions to upregulate expression of the growth factor receptor *IGF1R*.

Small-molecule inhibitors of γ-secretase impair the proteolytic activation of NOTCH, but early clinical trial results with these agents in relapsed/refractory T-cell ALL have been disappointing. Investigation of mechanisms of resistance to NOTCH1 inhibition has revealed several potential strategies for therapeutic intervention. Activation of the phosphoinositide-3-kinase (PI3K)-AKT pathway, which commonly results from loss of its negative regulator *PTEN* in T-cell ALL, provides one mechanism for resistance to NOTCH1 inhibition. The PTEN-PI3K-AKT pathway also mediates resistance to MYC inhibition in this disease. However, work in a murine model of Kras-induced T-ALL, where leukemias commonly acquire activating *NOTCH1* mutations and are sensitive to PI3K inhibitors, revealed that the development of resistance to PI3K inhibition was unexpectedly associated with the loss of oncogenic NOTCH1 signaling. This finding thus raises the possibility that dual PI3K-NOTCH1 inhibition may actually promote the emergence of drug resistance. Additional studies are needed to define the optimal strategy for clinical application of NOTCH1 and PI3K inhibition in patients with T-cell ALL.

Recent work has also revealed that some T-cell ALL cases in which the bulk cell population is sensitive to NOTCH1 inhibition harbor minor populations of so-called “persister” cells that are resistant to NOTCH1 inhibitors. This “persister” state is not driven by genetic mutations but is instead a reversible cellular state characterized by chromatin compaction. These NOTCH1 inhibitor-resistant cells maintain the expression of *MYC*, a crucial downstream target of *NOTCH1*, despite effective inhibition of NOTCH1 activity. However, the survival of these cells is specifically dependent on BRD4, a transcriptional regulator whose ability to bind acetylated chromatin can be specifically inhibited using small molecules. Combination therapy with inhibitors of both BRD4 and NOTCH1 can block the emergence of this resistance mechanism, and this approach has promising in vivo activity in preclinical models.

MYC Mutations in Mature B-Cell Lymphoblastic Leukemia

As reviewed previously in this chapter, mature B-cell ALL is characterized by chromosomal translocations that place the *MYC* coding sequence under the control of *Ig* gene-regulatory elements. Although the *MYC* coding region is not structurally altered by these translocations in most cases, point mutations of *MYC* commonly arise in these tumors at codons 58 or 62. These codons encode phosphorylation sites that regulate the activity and proteasomal degradation of MYC. These mutations lead not only to the aberrant stabilization of MYC protein but also inhibit the ability of MYC to activate apoptosis, while its ability to stimulate proliferation remains intact.

Mutations of Histone-Modifying Enzymes

DNA exists in cells in complex with histone proteins and other molecules in a complex known as chromatin. Post-translational modifications of histone proteins play prominent roles in the regulation of chromatin structure. Chromatin structure at individual loci can be broadly categorized as euchromatin, or “open” chromatin where transcription factor binding sites in DNA are readily accessible to the transcriptional machinery, or heterochromatin, where chromatin is compacted and DNA is generally not accessible to the transcriptional machinery. Alternations in chromatin structure can have profound effects on the gene expression program activated by transcription factors. Several enzymes that catalyze covalent histone modifications are recurrently mutated in ALL, highlighting a central role for dysregulation of chromatin structure in human leukemogenesis.

KMT2A Fusion Genes

Translocations involving the *KMT2A* gene (previously known as *MLL*) on chromosome 11q23 occur in approximately 80% of infant ALL cases, 5% of AML cases, and 85% of secondary AML cases that occur in patients treated with topoisomerase II inhibitors. *KMT2A* is the human ortholog of the *Drosophila* trithorax gene. Trithorax proteins are positive regulators of homeobox gene expression and act antagonistically to polycomb proteins. WT KMT2A positively regulates *HOX* gene expression and is required for both primitive and definitive hematopoiesis. WT KMT2A is a member of a large transcriptional regulatory complex, together with histone deacetylases and members of the SWI/SNF chromatin-remodeling complex.

The KMT2A protein undergoes proteolytic processing by Taspase1, a specialized protease that cleaves the KMT2A protein into N-terminal ($KMT2A^N$) and C-terminal ($KMT2A^C$) fragments that remain associated through intramolecular protein–protein interaction domains. $KMT2A^N$ contains several DNA-binding domains, including AT-hook domains that nonspecifically bind the minor groove of DNA, a methyltransferase homology region (CxxC domain) that specifically binds unmethylated DNA, four plant homeodomain zinc fingers with an embedded bromodomain, and a transcriptional repression domain. The C-terminal fragment $KMT2A^C$ contains a transcriptional activation domain that recruits the histone acetyltransferase cAMP response element-binding protein (CBP) and a SET domain that is responsible for its histone 3 lysine 4 (H3K4) methyltransferase activity.

WT KMT2A encodes an H3K4 lysine methyltransferase, and H3K4 methylation is associated with transcriptional activation. *KMT2A* fusion oncogenes result from translocations whose breakpoints cluster between exons 5 and 11 of *KMT2A*, and the resultant fusion proteins retain the N-terminal region of KMT2A, including the AT-hook and CxxC domains that bind DNA in a sequence-nonspecific manner. By contrast, the C-terminal domains that mediate the association of WT KMT2A with its endogenous chromatin-remodeling complex and its H3K4 methyltransferase activity are invariably lost from oncogenic KMT2A fusion proteins. Instead, the C-terminus of KMT2A fusion proteins is provided by one of more than 60 different translocation partners, with common translocations such as the t(4;11), t(9;11), and t(11;19)(q23;p13.3) resulting in the in-frame fusion of KMT2A to AF4, AF9, and ENL, respectively. The unrelated t(11;19)(q23;p13.1) translocation results in the fusion of KMT2A to ELL, the RNA polymerase II elongation factor.

Formal proof that *KMT2A* fusions play a critical role in the development of leukemias has come from the generation of murine models of *KMT2A*-induced leukemias. Chimeric mice harboring a *KMT2A–AF9* fusion gene generated by homologous recombination developed leukemias with a latency of 4 to 12 months. Retroviral transduction of *KMT2A–ENL, KMT2A–ELL,* and *KMT2A–CBP* fusion genes in hematopoietic precursors induces transformation upon transplantation into recipient mice. Similar results were obtained with a model in which chromosomal translocations involving the *KMT2A* locus are induced by directed interchromosomal recombination in mice, a strategy that reproduces experimentally the initiating events in the pathogenesis of *KMT2A*-rearranged leukemias. Interestingly, the introduction of *KMT2A–AF9* into committed granulocyte-macrophage progenitors in the mouse leads to the reactivation of a subset of genes normally expressed only in HSCs and transforms these committed precursors into AML leukemic stem cells by imparting the properties of self-renewal, suggesting that the leukemogenic lesion in *KMT2A*-rearranged leukemia might occur in a committed progenitor rather than in a pluripotent HSC.

KMT2A-rearranged B-lineage leukemias have a characteristic gene expression signature that includes the upregulation of several *HOX* genes and the expression of numerous myeloid markers. Both early B- and T-cell ALLs with *KMT2A* rearrangements showed a characteristic upregulation of specific *HOX* genes, including *HOXA9, HOXA10,* and *HOXC6,* and the *HOX* gene regulator *MEIS1*. These results, together with the demonstration that *HOXA9* plays important roles in the transformation of hematopoietic precursors by *KMT2A* fusion oncogenes in murine leukemia models, emphasize the central role of *HOX* gene dysregulation in the pathogenesis of *KMT2A*-rearranged leukemias. Additionally, as discussed later in this chapter, overexpression or activating mutations of the *FLT3* receptor tyrosine kinase (RTK) are frequent in *KMT2A*-rearranged leukemias.

Until recently, the precise mechanisms mediating the oncogenic activity of KMT2A fusion proteins were unclear because *KMT2A* translocation partners have no sequence similarity. However, recent work has shown that several distinct *KMT2A* translocation partners are functionally linked through their association in protein complexes that regulate transcriptional elongation. Oncogenic KMT2A-fusion proteins have been implicated in the DOT1L, SEC, and PAFc transcriptional complexes. The DOT1L complex consists of DOT1L, a histone H3 lysine 79 (H3K79) methyltransferase, and multiple KMT2A fusion partners, including AF9, ENL, and AF10. The SEC (also known as p-TEFb or AEP) complex consists of a CDK9 and cyclin T heterodimer (known as p-TEFb) that phosphorylates RNA polymerase II, interacts with several KMT2A fusion partners, including ENL, ELL, AF4, and AF5, and co-purifies with several KMT2A fusion proteins. PAFc, the polymerase-associated factor complex, regulates RNA polymerase II and associates with the amino terminus of both WT KMT2A and KMT2A fusions.

The observation that *DOT1L* interacts with multiple KMT2A translocation partners suggests that KMT2A fusion proteins may drive ectopic gene expression through recruiting excessive *DOT1L* activity to their target loci. *DOT1L* encodes a histone H3K79 methyltransferase, and many of the target genes directly upregulated by oncogenic KMT2A fusions are characterized by aberrant H3 lysine 27 (H3K27) methylation, including the 5′ *HOXA* cluster genes and *MEIS1*. Interestingly, the DOT1L methyltransferase is required for the transformation of murine bone marrow progenitors by KMT2A fusion oncoproteins, but it plays a less prominent role in normal hematopoiesis.

The oncogenic activity of KMT2A fusions also requires their physical interaction with Menin, the tumor suppressor protein encoded by the multiple endocrine neoplasia 1 (*MEN1*) gene. Menin binds an N-terminal domain of KMT2A that is conserved in all KMT2A fusion proteins. Moreover, abrogating the interaction of Menin with KMT2A, either by deleting Menin or by mutating the Menin-binding domain of KMT2A, impairs both transcriptional and oncogenic functions of KMT2A fusions. These findings spurred the development of small-molecule inhibitors of the KMT2A-menin interaction. Studies of small molecular inhibitors have provided critical insight into the mechanism by which KMT2A-Menin inhibition acts through the displacement of KMT2A chromatin occupancy at select target genes (Fig. 66.2) and have demonstrated promising activity in preclinical models, both in vitro and in vivo, including complete eradication of leukemia in a patient-derived xenograft model of *KMT2A*-rearranged acute leukemia, providing the rationale for early phase clinical trials of Menin inhibitors in relapsed/refractory *KMT2A*-rearranged acute leukemias.

The presence of *KMT2A* rearrangements is associated with inferior outcomes despite aggressive chemotherapy, especially in infants with ALL, 80% of whom present with *KMT2A*-rearrangements.

PRC2 Mutations in T-Cell Acute Lymphoblastic Leukemia

The PRC2 is a transcriptional repressor complex best known as a "writer" of histone H3K27 methylation, a chromatin mark associated with transcriptional repression. Up to 25% of T-cell ALL cases harbor inactivating mutations of core components of the PRC2, including *EZH2, SUZ12,* and *EED*. EZH2 deficiency is sufficient to initiate T-cell leukemogenesis in murine models, implicating PRC2 as a tumor suppressor in this disease. Genome-wide analysis of NOTCH1 occupancy and histone methylation patterns have revealed that NOTCH1 binding is associated with loss of the repressive histone mark placed by the PRC2 complex, H3K27 trimethylation. Recent work has revealed that the H3K27 "eraser" demethylase JMJD3 (also known as KDM6B) is a component of the NOTCH1 transcriptional complex. These data thus support a model in which the NOTCH1 recruits the H3K27 "eraser" demethylase JMJD3 to its target genes, where it antagonizes the activity of the H3K27 "writer" PRC2. Thus, one pathogenic consequence of PRC2 inactivation in T-cell ALL may be the release of inhibition of oncogenic NOTCH1 signaling. Interestingly, a small-molecule inhibitor whose effects include inhibition of JMJD3 function has therapeutic activity in T-cell ALL, thus suggesting that JMJD3 inhibition may be a potential therapeutic strategy for patients with PRC2-mutant T-cell ALL. Additionally, recent work has demonstrated that PRC2 plays a role in chemotherapy resistance via inhibition of mitochondrial apoptosis. In T-ALL cells, knockdown of *EZH2*, a core component of the PRC2 complex, resulted in resistance to multiple chemotherapy agents that are commonly used in T-cell ALL therapy. RNA sequencing and in vitro functional studies revealed downregulation of CRIP2 and the mitochondrial chaperone protein TRAP1 in PRC2 deficient T-cell ALL cells, suggesting that these play a key role in apoptosis resistance and treatment response and may provide a novel therapeutic strategy in PRC2-deficient T-cell ALL.

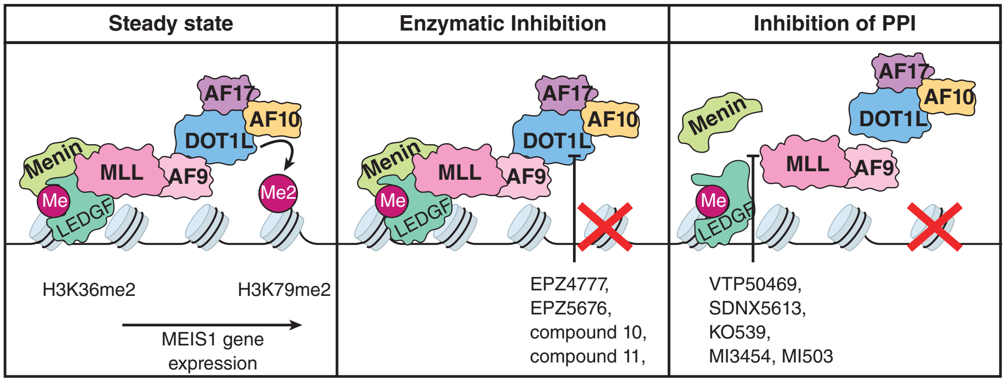

Figure 66.2 MODEL FOR THE CONSEQUENCES OF DOT1L VERSUS MENIN INHIBITION FOR THE INTEGRITY OF THE MLL-AF9 COMPLEX ON CHROMATIN. At steady state, the intact MLL-AF9 complex stably binds to its target genes via Menin and recruits the DOT1L complex to drive histone H3 lysine 79 methylation (H3K79me2) and gene expression of canonical target genes (e.g., *MEIS1*) (*left*). DOT1L inhibition removes H3K79me2 by blocking the enzymatic activity of the methyltransferase while leaving the complex largely intact (*middle*). Inhibition of the Menin-MLL interaction disrupts the integrity of the MLL-AF9 complex, leading to a more rapid and profound response (*right*). *(Adapted from Perner F, Armstrong SA. Targeting chromatin complexes in myeloid malignancies and beyond: from basic mechanisms to clinical innovation. Cells. 2020;9:2721, with permission).*

Focal Activating Mutations of Noncoding Gene-Regulatory Elements

Activating mutations of cis-acting gene-regulatory elements are common events in ALL pathobiology. This mechanism was first revealed through the investigation of recurrent translations that juxtapose the protein-coding sequences of *MYC* with *Ig* enhancer elements in mature B-cell ALL (Burkitt leukemia), as discussed earlier in this chapter. However, mono-allelic oncogene overexpression often occurs in the absence of identifiable chromosomal translocations, suggesting the existence of unrecognized mutations of cis-acting gene-regulatory elements. Our ability to identify pathogenic mutations of non-protein-coding elements has been hampered by the difficulty of distinguishing pathogenic "driver" mutations from nonspecific "passenger" events that represent nonspecific consequences of genetic instability, which are much more common in cancer genomes. Two recent studies provide experimental paradigms for the identification of such pathogenic mutations of gene-regulatory elements based on co-localization of genetic lesions with markers of active gene-regulatory elements.

TAL1 Super-Enhancer Mutations in T-Cell Acute Lymphoblastic Leukemia

Advances in the ability to map transcription factor occupancy and chromatin modifications genome-wide have revealed the presence of unusually dense clusters of enhancer elements at select genomic locations. These elements have been termed super-enhancers (also stretch enhancers or locus control regions) and are characterized by dense and broad occupancy by core components of the transcriptional machinery, such as Mediator, as well as histone marks associated with active enhancer elements, including histone H3K27 acetylation. Super-enhancers have been implicated in the expression of genes responsible for cellular identity in normal and malignant cells.

Recent work has revealed the presence of focal mutations affecting a specific hotspot in a noncoding locus 23 kb upstream of the *TAL1* oncogene in 5% of T-cell ALL cases. These mutations uniformly introduce a binding motif for the MYB transcription factor, and this occurs at a locus that already harbors binding motifs for core components of the TAL1 complex, including TAL1 itself, RUNX1, and GATA3. These mutations lead to the discovery that the *MYB* oncogene is a core component of the TAL1 complex. Indeed, the introduction of this novel MYB binding site is sufficient to recruit the entire TAL1 transcriptional complex to this locus (Fig. 66.3), leading to the generation of an aberrant super-enhancer that drives aberrant overexpression of TAL1 specifically from the mutated allele.

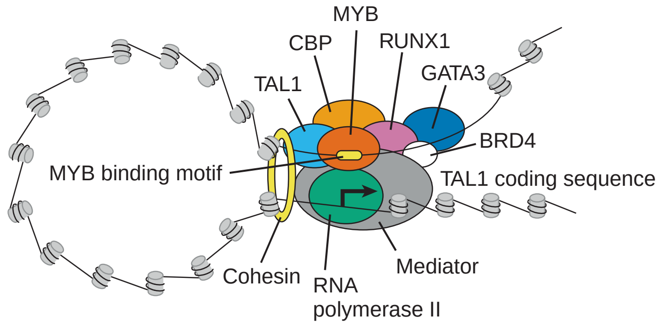

Figure 66.3 ONCOGENIC SUPER-ENHANCER IN T-CELL ALL. Noncoding insertion mutations upstream of TAL1 create binding sites for the MYB transcription factor, leading to the recruitment of core components of a major leukemogenic transcriptional complex containing RUNX1, GATA-3, and TAL1, and to the formation of a de novo super-enhancer that drives expression of the *TAL1* oncogene in a subset of T-cell ALL. *(Adapted from Hnisz D, Abraham BJ, Lee TI. Super-enhancers in the control of cell identity and disease. Cell. 2013;155(4):934–947).*

Duplications of the NOTCH-Driven Enhancer of MYC in T-Cell Acute Lymphoblastic Leukemia

Aberrant NOTCH1 activation is pathogenic, at least in part, due to NOTCH1-driven overexpression of *MYC*, as reviewed earlier in this chapter. Recent work has revealed an enhancer element downstream of *MYC* that is highly bound by NOTCH1 and is affected by recurrent somatic duplications in 3% of T-cell ALL. This enhancer forms a looping interaction with the *MYC* proximal promoter, and it drives NOTCH1-dependent overexpression of *MYC*. Mice in which this enhancer element has been deleted have a defect in T-cell development that specifically mimics that seen in mice with T-cell specific *MYC* inactivation. Moreover, murine bone marrow cells lacking this enhancer element are completely resistant to leukemic transformation by NOTCH1. Finally, duplication of this enhancer element drives increased gene expression in a reporter assay, suggesting that this enhancer duplication is pathogenic because it potentiates signaling through the oncogenic NOTCH1-MYC axis.

Aberrant Growth Factor Signaling

BCR-ABL1 in Acute Lymphoblastic Leukemia

The Philadelphia (Ph) chromosome, which arises from the t(9;22)(q34;q11), was originally identified in patients with chronic myelogenous leukemia (CML); however, it is also found in about 2% to 4% of childhood cases and 20% of adult cases of ALL, which are almost always of the B-cell ALL subtype. The t(9;22) generates a *BCR–ABL1* fusion gene consisting of 5′ (upstream) sequences from *BCR* and 3′ (downstream) sequences of *ABL1*. The t(9;22) breakpoints on the distal tip of the long arm of chromosome 9 are scattered over a distance of nearly 200 kb within the first intron of the *ABL* proto-oncogene, upstream of the tyrosine kinase domain. The breakpoints in the *BCR* gene on chromosome 22 cluster in two separate regions of that gene, known as the major breakpoint cluster region (M-bcr) or minor breakpoint cluster region (m-bcr). In two-thirds of cases of Ph-positive ALL, the breakpoint in the *BCR* gene occurs in the m-bcr, but in all cases of CML and about one-third of cases of ALL, the breaks occur in the M-bcr. The fusion transcript more commonly present in ALL (m-bcr) encodes a 190-kd protein (p190), whereas the transcript found in CML and in some cases of ALL (M-bcr breakpoint) encodes a 210-kd hybrid protein (p210). Both types of fusions generate chimeric oncoproteins that are activated as a tyrosine-specific protein kinase, similar to the v-abl protein.

The ABL1 tyrosine kinase is localized both in the nucleus and in the cytoplasm of proliferating cells. It is normally activated by DNA damage downstream of ATM and appears to promote p53-mediated growth arrest. Mice deficient in ABL develop a wasting syndrome and die soon after birth. In contrast to the nuclear and cytoplasmic distribution of normal ABL, the BCR–ABL1 fusion oncoprotein has a cytoplasmic location and shows increased tyrosine kinase activity. When expressed in murine hematopoietic precursors, both p190 and p210 transform hematopoietic cells in vitro and induce a syndrome similar to CML in mice. Transformation by the BCR–ABL1 oncoprotein involves activation of the RAS–MAPK (mitogen-activated protein kinase) pathway, PI-3 and JUN kinases, c-CBL and CRKL, JAK–STAT, NFκB (nuclear factor kappa-B), Src, and cyclin D1. The BCR–ABL1 oncoprotein affects multiple aspects of cell homeostasis, including apoptosis, differentiation, and cell adhesion. An important cellular effect of BCR–ABL1 is the induction of cellular resistance to DNA damage agents such as cytostatic drugs and irradiation. After DNA damage, BCR–ABL1 extends the duration of the G2/M cell cycle checkpoint and facilitates DNA repair. It also upregulates the antiapoptotic *BCL-XL* gene, contributing to the suppression of apoptotic cell death.

The presence of the Ph chromosome historically was associated with an extremely poor prognosis in ALL patients despite treatment with intensified chemotherapeutic regimens. Better outcomes were achieved with allogeneic stem cell transplantation in first complete remission, but overall prognosis remained inferior to other ALL subtypes. The development of imatinib mesylate, a pharmacologic tyrosine kinase inhibitor targeting the BCR–ABL1 oncoprotein, has transformed the management of Ph-positive ALL. The utility of imatinib as a single agent for Ph-positive ALL is limited by the rapid development of drug resistance. However, the combination of imatinib and other BCR-ABL1 kinase inhibitors, such as dasatinib, with cytotoxic chemotherapy has led to significant improvements in outcome for patients with Ph-positive ALL over the last two decades.

Resistance to tyrosine kinase inhibitors can emerge in Ph-positive lymphoblasts, most commonly because of point mutations in the kinase domain of *BCR–ABL1*. As a result, a series of novel BCR–ABL1 kinase inhibitors have been developed that retain activity against many of these mutant oncoproteins. Although not all *BCR–ABL1* mutations that confer resistance can be overcome with newer agents, the potential of these newer BCR–ABL inhibitors with broader specificity to further improve outcomes is actively being investigated. Additionally, a novel pathway mediating resistance to BCR–ABL1 inhibition has been uncovered in Ph-positive ALL. Upon BCR–ABL1 inhibition, these cells markedly upregulate expression of the *BCL6* transcription factor, a well-known oncogene that is often translocated in diffuse large B-cell lymphomas. *BCL6* then blocks activation of the p53 pathway via transcriptional repression of *ARF* and thus blocks the therapeutic efficacy of monotherapy with imatinib in Ph-positive ALL cells. Importantly, inhibition of BCL6 activity genetically or using a peptide inhibitor of BCL6 has demonstrated marked activity in patient-derived BCR–ABL xenografts grown in immunodeficient mice, highlighting the therapeutic relevance of these findings.

BCR-ABL1-Like Acute Lymphoblastic Leukemia

Analysis of gene expression signatures of patients with ALL has led to the identification of a subtype of B-cell ALL termed BCR-ABL1-like or Ph chromosome-like (Ph-like) ALL. These cases were identified because they lack BCR-ABL1 translocations yet are characterized by a gene expression signature nearly identical to that of BCR-ABL1 ALL. Ph-like ALL occurs in approximately 15% of B-ALL, increasing in frequency with age, and has been associated with an inferior prognosis compared to other subtypes of B-cell ALL, similar to BCR-ABL1 ALL. One genetic feature common to both BCR-ABL1 and BCR-ABL1-like ALL is the deletion of the *IKZF1* tumor suppressor. Approximately half of the cases of Ph-like ALL contain *CRLF2* genomic alterations and half of those cases contain concomitant *JAK* mutations. The remaining cases of Ph-like ALL have been characterized by rearrangements involving various kinases, including *ABL1, ABL2, CSF1R, JAK2,* and *PDGFRB* (Fig. 66.4). In a small subset of cases, rearrangements leading to overexpression of the erythropoietin receptor *EPOR* have been observed. These findings have important clinical implications, as many of these mutations are potentially targetable with clinically relevant inhibitors

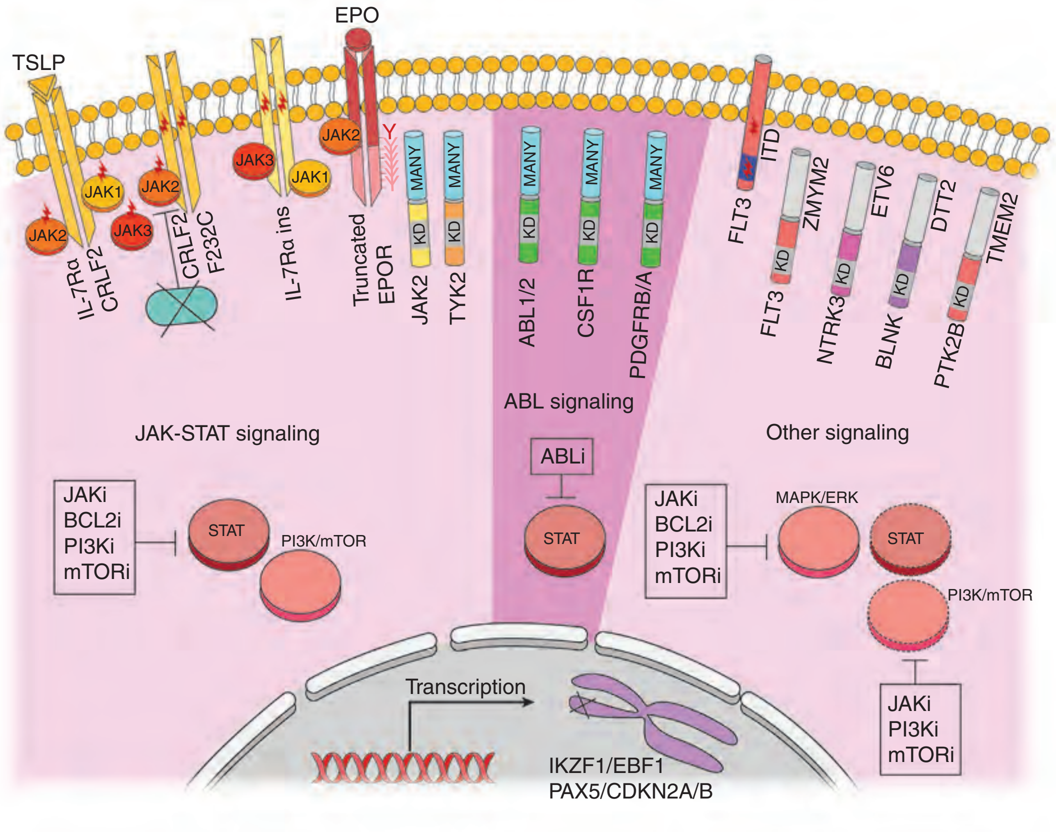

Figure 66.4 ABERRANT ACTIVATION OF SIGNAL TRANSDUCTION PATHWAYS IN BCR-ABL1-LIKE ALL. Deregulation of JAK2, ABL, and other signaling pathways in BCR-ABL1-like ALL is caused by activating mutations (*lightning bolts*), fusion genes, or genomic deletions (*X*) leading to overexpression of cytokine receptors (e.g., CRLF2, IL-7, EPOR), expression of constitutively active receptors (e.g., EPOR), mislocalized and constitutively active kinases. Some downstream signaling pathways are shown, as well as potential targets for therapeutic intervention with small-molecule inhibitors (i). *(Adapted from Iacobucci I, Mullighan CG. Genetic basis of acute lymphoblastic leukemia. J Clin Oncol. 2017;35:975, with permission.)*

NUP214–ABL1 in T-Cell Acute Lymphoblastic Leukemia

Although the BCR–ABL1 translocation is rare in T-cell ALL, amplified episomes containing *NUP214–ABL1* fusion genes have been described in approximately 6% of children and adults with T-cell ALL. These episomes appear to arise via a mechanism in which the genomic region of chromosome 9q34, which contains both the *NUP214* and *ABL1* genes, is circularized in a manner that leads to the fusion of these two genes. The breakpoint in the *ABL1* gene in all of these cases occurs in intron 1, which is the same breakpoint observed in Ph-positive CML and B-cell ALL, but the *NUP214* breakpoints are variable. The WT NUP214 protein is a component of the nuclear pore complex and may contribute oligomerization motifs to the *NUP214–ABL1* fusion oncogene. The NUP214-ABL1 fusion protein has constitutively activated ABL1 tyrosine kinase activity, which is inhibited by the BCR–ABL kinase inhibitor imatinib, suggesting the potential therapeutic role of imatinib or other tyrosine kinase inhibitors in these patients.

B-Cell Receptor Signaling in Acute Lymphoblastic Leukemia

Despite its importance in the molecular pathogenesis of mature B-cell lymphomas, the role of B-cell receptor signaling in ALL was poorly understood. However, in one study, 10% to 15% of cases of B-cell ALL were characterized by active signaling through the B-cell receptor. Such B-cell receptor-positive cases were identifiable by expression of the Ig μ heavy chain or of BCL6 protein on flow cytometry and were strongly associated with the presence of the *TCF3-PBX1* rearrangement or 6q21 deletion, but they are rare in other ALL subsets. Interestingly, the oncogenic *TCF3-PBX1* translocation itself directly binds and upregulates genes encoding key components of the B-cell receptor in these cases. Active B-cell receptor signaling leads to downstream activation of SRC, SYK, and PI3K oncogenic signaling pathways. Importantly, these cases are sensitive to small-molecule inhibitors of kinases that mediate B-cell receptor signaling in preclinical models, thus providing a novel potential therapeutic strategy for these patients.

RAS Gene Mutations

Pioneering studies into the molecular etiology of cancer led to the identification of activated homologs of either *HRAS* or *KRAS* in human tumor DNA. These proto-oncogenes were originally identified on the basis of their homology with viral oncogenes. Gene transfer methods identified an additional member of the *RAS* gene family, called *NRAS*, that had not been observed as a component of a transforming retrovirus. Proto-oncogenes of the *RAS* family (*HRAS, KRAS,* and *NRAS*) encode 21-kDa proteins that are associated with the inner surface of the cytoplasmic membrane and are involved in growth factor receptor signaling. *RAS* proteins are guanosine nucleotide-binding proteins (G proteins) that are GTP-bound in their active form, and GDP-bound in their inactive form. The *RAS* proto-oncogenes are converted to the status of transforming oncogenes by somatic mutations that most commonly alter the amino acids specified by codons 12, 13, or 61. Mutated *RAS* genes lose their intrinsic GTPase activity, thus accumulating in their active, GTP-bound conformation, even in the absence of growth factor binding to surface receptors. Aberrant RAS-mediated signaling contributes to transformation through activation of the PI3K and MAPK pathways.

In ALL, mutations of codons 12, 13, or 61 of *NRAS* have been found in approximately 10% of patients, while *KRAS* mutations have been identified in 5% to 10% of patients. *RAS* mutations are considerably more common in specific molecular subsets of ALL. Up to 50% of cases of *KMT2A*-rearranged ALL harbor mutations of *NRAS* or *KRAS*, although these mutations can be subclonal and lost at relapse. *RAS* mutations have also been identified in approximately 30% of Down syndrome-associated B-cell ALL, and appear to be mutually exclusive of *JAK2* mutations in this setting. *RAS* mutations appear to be more frequently found in the setting of relapsed ALL and are associated with a poor prognosis in this setting. The development of an effective pharmacologic approach for direct inhibition of *RAS* has been elusive. However, recent studies in preclinical models of *RAS*-driven ALL have revealed the therapeutic potential of inhibitors of key downstream effectors of *RAS* signaling in ALL, including MEK and PI3K, thus providing a rationale for clinical trials testing such an approach for *RAS*-mutant ALL.

PTEN–PI3K–AKT Mutations in T-Cell Acute Lymphoblastic Leukemia

The *PI3K–AKT* signal transduction pathway, which is negatively regulated by the *PTEN* tumor suppressor, induces cellular growth and proliferation while inhibiting apoptosis and is aberrantly activated in a range of human cancers. In T-cell ALL, recent work has identified a very high frequency of mutational activation of oncogenic signaling through this pathway, most often via deletions or truncating mutations of *I*, but activating mutations of *PI3K* and *AKT* genes also occur. Moreover, deletions of *PTEN* have been found to predict treatment resistance in clinical specimens, and mutations within the *PI3K* pathway are associated with inferior clinical outcomes. Studies in zebrafish and patient-derived xenograft mouse models have identified that acquisition of *PI3K-AKT* pathway during clonal evolution of leukemic blasts leads to primary glucocorticoid resistance, an effect mediated by direct phosphorylation of the glucocorticoid receptor by *AKT*. In addition, both *MYC* and the *PI3K-AKT* pathway have been identified as key suppressors of the proapoptotic factor, *BIM*, which is required for mitochondrial apoptosis in normal T-cell development. Taken together, these findings thus suggest the potential clinical utility of *PI3K-AKT* pathway inhibitors in high-risk T-cell ALL.

FLT3 Mutations and Overexpression in Acute Lymphoblastic Leukemia

FLT3 encodes an RTK that is highly expressed in early hematopoietic precursors, where it plays important functional roles. Multiple studies have shown that activating mutations of *FLT3*, which lead to constitutive RTK activity even in the absence of ligand, are common in leukemic myeloblasts in patients with AML but are rare in adults with ALL. However, gene expression studies demonstrated high expression of *FLT3* in pediatric ALL cases that involve *KMT2A* gene rearrangements or high hyperdiploidy. Additionally, activating mutations were identified in 18% of infants with *KMT2A*-rearranged ALL, in 21% to 24% of hyperdiploid ALL cases, and in all three cases of the prothymic CD117/KIT$^+$ subtype of T-cell ALL in adults examined.

In the absence of the FLT3 ligand, WT FLT3 receptors are inactive because of autoinhibition mediated by the juxtamembrane domain of the receptor. Upon binding of FLT3 ligand, normal FLT3 receptors homodimerize, become activated by phosphorylation, and lead to the activation of signal transduction pathways that promote proliferation and cell survival. Activating mutations of FLT3 found in leukemias occur in two separate regions of the gene. In-frame tandem duplications in the juxtamembrane domain lead to loss of the autoinhibition mediated by this domain, with subsequent dimerization and receptor activation in the absence of FLT3 ligand. Alternatively, point mutations or insertions in the second tyrosine kinase domain of the FLT3 receptor lead to autophosphorylation and activation of downstream signaling in the absence of the FLT3 ligand. Small-molecule inhibitors of the FLT3 kinase lead to in vitro apoptosis in AML cell lines and *KMT2A*-rearranged ALL cell lines and are used clinically in *FLT3*-mutated AML, but a beneficial impact of these agents in ALL with *FLT3* mutations and/or overexpression has not been demonstrated.

CRLF2 and *JAK2* Mutations in B-Cell Acute Lymphoblastic Leukemia

The CRLF2 cytokine receptor binds its ligand, thymic stromal lymphopoietin (TSLP), as a heterodimeric complex with the IL-7 receptor subunit (IL-7R). TSLP–CRLF signaling plays physiologic roles during normal B-cell development and in inflammation. Mutations and rearrangements involving *CRLF2* have been observed in 5% to 10% of cases of pediatric B-ALL but are much more frequent in the Ph-like subtype and in Down syndrome patients (approximately 50% of each). The abnormalities that commonly lead to *CRLF2* overexpression include translocations of the *IGH* locus (chromosome 14) to *CRLF2* and interstitial deletions in pseudoautosomal regions of Xp22.3/Yp11.3, resulting in a *P2RY8-CRLF2* fusion. Aberrant *CRLF2* expression very frequently co-occurs with *JAK2* activating mutations, and these two genetic lesions collaborate to induce ligand-independent activation of downstream signal transduction pathways, suggesting that CRLF2 may act as a scaffold that is required for activation of oncogenic JAK–STAT signaling by *JAK2* mutations in B-cell ALL. In addition to co-occurring mutations in the JAK/STAT pathway, *CRFL2*-rearrangements frequently co-occurs with *IKZF1* gene deletions as well as mutations with the *RAS* pathway, leading to activation of *MAPK, PI3K*, and *mTOR* pathways. The exact mechanism by which these mutations cooperate with *CRLF2* rearrangements in B-cell ALL remains unknown. When first identified, *CRLF2* rearrangements were thought to portend a poor prognosis in pediatric B-cell ALL; however, more recent analyses suggest that this observation was due to their high frequency in Ph-like ALL and co-occurrence with *IKZF1* deletions but that CRLF2 rearrangements themselves are not independent predictors of adverse outcome.

Interleukin-7 Receptor Mutations in Acute Lymphoblastic Leukemia

The interleukin 7 receptor alpha (*IL7R*) is required for normal lymphoid development, with loss-of-function *IL7R* mutations leading to severe combined immunodeficiency. The IL-7R protein can heterodimerize with either IL2Rγ, resulting in the receptor for IL-7, or with CRLF2 to form the receptor for TSLP. Gain of function mutations characterized by either a serine-to-cysteine substitution at amino acid 185 within the extracellular domain or in-frame insertions and deletions in the transmembrane domain have been described in both B-cell and T-cell ALL. In the case of the point mutations, this permits the formation of a neomorphic disulfide bond between mutant IL-7R homodimers and leads to ligand-independent receptor dimerization and activation of downstream oncogenic signal transduction pathways, including JAK–STAT and PI3K–AKT. A potential therapeutic strategy to target oncogenic activation of mutant IL-7R proteins is the reduction of the neomorphic disulfide bond. Indeed, N-acetylcysteine, a reducing agent developed clinically for the treatment of acetaminophen overdose, has been shown to reduce the extracellular cysteine bond and inhibit signaling by mutant IL-7R proteins. Downstream activation of the JAK–STAT pathway in gain of function IL7R mutated ALL would suggest that inhibition of JAK2 with ruxolitinib may be an effective therapeutic approach. Preclinical data has confirmed that ruxolitinib treatment has robust activity in murine xenograft models of Ph-like ALL, including those with *IL7R* mutations. This treatment approach is being studied in a Phase 2 study of de novo JAK pathway mutant Ph-like childhood ALL through the Children's Oncology Group.

Tumor Suppressor Gene Inactivation

Much attention has been focused on tumor suppressors, whose loss of function via deletion or mutational inactivation leads to malignant transformation. Knudson first proposed that inactivation of both alleles of a single locus is needed to initiate the development of retinoblastoma, basing his hypothesis on the observed frequencies of hereditary and sporadic forms of this disease. Allelic loss of defined regions of many different chromosomes has been linked to specific types of human tumors. By analogy with the findings in retinoblastoma, a reasonable hypothesis is that each of these regions harbors a tumor suppressor gene whose product is uniquely involved in the inhibition of cell cycle progression and promotion of terminal differentiation of the normal cells that give rise to these different types of tumors.

p53 and *CDKN2A* Mutations

p53 (also known as *TP53*) is a classic tumor suppressor gene whose activation induces apoptosis, cell cycle arrest, or senescence in response to distinct stimuli, including DNA damage or aberrant oncogene activation. p53 is mutated or deleted in a wide variety of human tumors and occurs as a heritable cause of cancer in families with Li-Fraumeni syndrome. p53 is inactivated in a variety of hematopoietic malignancies, including mature B-cell ALL, but is mutated or deleted in fewer than 3% of pediatric B-cell or T-cell ALL cases at diagnosis. Recently, large-scale genomic profiling of childhood B-cell ALL has revealed germline p53 mutations in about 2% of cases sequenced (which is discussed further in the following sections), thus adding B-cell ALL to the constellation of malignant neoplasms that patients with Li-Fraumeni syndrome are at risk for developing. While mutations in p53 are overall uncommon in B-cell ALL, they are characteristic of low hypodiploid ALL, occurring in more than 90% of cases with this specific subtype. About half of the p53 mutations observed in hypodiploid ALL are germline and the rest are somatic. Additionally, p53 mutations are seen in approximately 25% of relapsed T-cell ALL cases, as well as in association with early treatment failure, suggesting a role for p53 inactivation in the development of resistant disease.

Despite the rarity of p53 mutations in ALL specimens at the time of diagnosis, the p53 pathway is commonly inactivated by loss-of-function mutations of the *CDKN2A* locus in ALL. *CDKN2A* encodes two distinct tumor suppressor proteins, ARF (also known as p14ARF in humans and p19ARF in mice) and p16INK4a. ARF is induced by oncogene stress, such as acute *MYC* overexpression, and it binds and sequesters MDM2, leading to p53 activation. p16INK4a is a cyclin-dependent kinase inhibitor, a family of proteins that also include p15INK4B, p18INK4C, p19INK4D, p21, p27, and p57. These constitute a family of tumor suppressors that negatively regulate the cell cycle by inhibiting CDK phosphorylation of pRB. In particular, human leukemia and lymphoma show a high frequency of 9p21 deletions involving both the p16INK4A/p14ARF and the p15INK4B loci. Epigenetic silencing of these tumor suppressor genes through hypermethylation of their promoter sequences represents an alternative mechanism of gene inactivation. Although p16INK4A/p14ARF and p15INK4B are homozygously deleted in 20% to 30% of B-cell ALL cases and in 70% to 80% of T-cell ALL cases, epigenetic silencing of the p15INK4B promoter has been observed in 44% of primary B-lineage ALLs.

FBXW7 and Cyclin C in T-Cell Acute Lymphoblastic Leukemia

FBXW7 (also known as *FBW7*) is an E3 ubiquitin ligase that targets the transcriptionally active intracellular form of NOTCH1 (ICN), MYC, and cyclin E for degradation, and this gene is inactivated by mutation or deletion in approximately 10% of T-cell ALL cases. In T-cell ALL cell lines, *FBXW7* mutation or homozygous deletion leads to resistance of NOTCH1 pathway inhibition by γ-secretase inhibitor therapy, presumably because intracellular NOTCH protein levels remain high in the absence of FBXW7-mediated degradation despite inhibition of γ-secretase activity. Additionally, tumor-derived *FBXW7* mutations maintain their ability to bind MYC but do not lead to its degradation and may act as dominant-negative mutants that protect MYC from degradation. *FBXW7* also targets the antiapoptotic protein MCL1 for proteasomal degradation in T-cell ALL, providing an additional oncogenic consequence resulting from the inactivation of the *FBXW7* tumor suppressor that may provide a novel therapeutic strategy using MCL1 inhibitors.

Recent work has implicated cyclin C as a key component of the *FBXW7*-dependent pathway that mediates the degradation of NOTCH1. Cyclin C, which was originally identified as a growth-promoting cyclin, is involved in recurrent heterozygous deletions in human T-cell ALL. In a murine model, loss of one cyclin C allele accelerates the onset of NOTCH1-induced T-cell ALL, implicating this gene as a tumor suppressor. Mechanistically, cyclin C binds and activates the cyclin-dependent kinases CDK18, CDK8, and CDK3 to phosphorylate the intracellular domain of NOTCH1 and to promote its FBXW7-mediated proteasomal degradation. Thus, cyclin C deficiency and FBXW7 are both key components of a degradation pathway that controls physiologic NOTCH1 activity. The model that emerges from these findings is that impaired function of either of these tumor suppressors promotes T-cell oncogenesis by inducing aberrant nuclear accumulation of transcriptionally active NOTCH1.

PAX5 and Other B-Cell Developmental Gene Alterations in B-Cell Acute Lymphoblastic Leukemia

A high-resolution genome-wide analysis of B-cell ALL cases using single nucleotide polymorphism arrays identified copy number alterations in a number of genes that play important roles in B-cell development. Genes involved in B-cell development were found to be altered by deletion, amplification, mutation, or rearrangement in 40% of cases of B-cell ALL. The most common abnormalities identified were deletions of *PAX5*, and upon further analysis in other cases, other mechanisms that led to the inactivation of *PAX5* were identified. These included a number of translocations that led to fusion proteins that maintained the ability to bind to *PAX5* transcriptional targets but lost regulatory ability, thus having dominant-negative activity, and inactivating point mutations that altered the transcriptional activity of *PAX5*. As discussed later in this chapter, a recurrent germline *PAX5* mutation affecting Gly183 in the octapeptide domain of the gene has been identified in two unrelated kindreds, thus implicating *PAX5* in an autosomal dominant leukemia predisposition syndrome. Deletions were also detected in the *TCF3, EBF1, LEF1, IKZF1,* and *IKZF3* genes, all of which play important roles in B-cell development. More recently, genomic analyses of pediatric and adult B-cell ALL have identified two specific *PAX5* subtypes. The first, *PAX5*alt, was found in 7% of cases and is characterized by diverse genetic alterations, including rearrangements, intragenic amplifications, and mutations. The second is characterized by a specific *PAX5* SNV that results in a nonsynonymous amino acid substitution of Arginine for Proline at position 80 (p.P80R). This particular residue is essential for the binding of PAX5 to its targets and results in a nonfunctional protein and B-cell maturation arrest. Interestingly cases with PAX5 p.P80R almost uniformly lost the wildtype allele. In total, PAX5alt and PAX5 p.P80R account for about 9% of the B-other ALL subtype and are associated with intermediate-poor outcomes in both children and adults with B-cell ALL.

IKZF1 Deletions in B-Cell Acute Lymphoblastic Leukemia

IKZF1 (Ikaros) is a DNA-binding transcription factor that is required for the development of all lymphoid lineages, and expression of a dominant-negative isoform of *IKFZ1* in mice was shown to lead to T-cell lymphomas. However, the role of *IKZF1* in human leukemias was not appreciated until genomic analyses of B-cell ALL patient samples revealed *IKZF1* deletions in 16% to 29% of pediatric samples. *IKZF1* deletions are strongly associated with BCR–ABL1-positive ALL and Ph-like ALL and are also acquired at the transformation of CML to ALL (lymphoid blast crisis). *IKZF1* deletions are associated with an inferior 5-year EFS and an increased 5-year cumulative incidence of relapse, even in children with low end-induction minimal residual disease (MRD), and on multivariable analyses have been shown to be an independent predictor of adverse outcome. Interestingly, recent work has identified co-occurring mutations, which have a significant impact on the prognostic significance of *IKZF1* mutations. B-cell ALL cases harboring deletions of *IKZF1* that occur in combination with deletions of *CDKN2A, CDKN2B, PAX5,* or *PAR1* and in the absence of an *ERG* deletion, termed *IKZF1*$^{\text{plus}}$, had significantly inferior outcome than in B-cell ALL cases that harbor an *IKZF1* deletion but do not meet criteria for *IKZF1*$^{\text{plus}}$.

Inactivation of *LEF1* in T-Cell Acute Lymphoblastic Leukemia

The LEF1 transcription factor, a member of the LEF/TCF (lymphoid enhancer-binding factor/T-cell-specific transcription factor) family of DNA-binding transcription factors, is best known for its role as a positive mediator of β-catenin transcriptional activity, a well-established oncogene. Genomic analyses have identified mono- and biallelic deletions and truncating mutations of *LEF1* in 18% of primary T-cell ALL patient samples, implicating *LEF1* as a T-cell ALL tumor suppressor. *LEF1* inactivation is associated with a very young age at diagnosis, T-cell differentiation arrest at an early cortical stage of T-cell development, and activating *NOTCH1* mutations. Moreover, T-cell ALL cases with *LEF1* inactivation are characterized by very high expression of MYC mRNA, a surprising finding given that LEF/TCF transcription factors transactivate MYC expression when bound to β-catenin. In addition to their well-established functions as transcriptional activators, LEF/TCF transcription factors can also act as transcriptional repressors when bound to Groucho/TLE family members in the absence of β-catenin activation. Although the precise mechanisms responsible for the pathogenic effect of *LEF1* inactivation in T-cell ALL have not yet been established, one potential explanation is that *LEF1* may actively repress *MYC* in T-cell ALL cells lacking β-catenin activation, and that *LEF1* inactivation in this context may promote maximal *MYC* overexpression downstream of other oncogenic lesions that drive *MYC* overexpression, such as *NOTCH1* mutations.

BCL11B Inactivation in T-Cell Acute Lymphoblastic Leukemia

The *BCL11B* transcription factor is required for normal T-cell development. In murine T-cell progenitors, inactivation of *BCL11B* leads to developmental arrest at DN stages, acquisition of NK-like features, and aberrant self-renewal activity. By contrast, knockdown of *BCL11B* in human cells revealed a species-specific transcriptional program, but the overall effect demonstrated conservation of the negative regulatory effect of *BCL11B* on stem, myeloid, and NK genes. Monoallelic *BCL11B* deletions or point mutations have been identified in 9% to 16% of primary T-cell ALL patient samples. The point mutations identified typically occur within the DNA-binding domains of *BCL11B* and are predicted to disrupt their ability to bind DNA. Moreover, previous work in murine models has shown that *BCL11B* suppresses T-lymphoblastic malignancies induced by p53 haploinsufficiency, radiation, or the *BCR–ABL1* oncogene, and *BCL11B* inactivation is a particularly common cooperating lesion in murine T-cell ALL induced by the *TLX1* oncogene or by *ATM* deficiency. In human T-cell ALL, recurrent cryptic t(5;14)(q35;q32) translocations juxtaposing *BCL11B* and *TLX3* have been described, resulting in *BCL11B* gene-regulatory elements driving overexpression of *TLX3*. These translocations were long thought to be pathogenic because of the resultant overexpression of the *TLX3* oncogene. However, these recent findings indicate that both *BCL11B* inactivation and *TLX* oncogene overexpression are important pathogenic consequences of this translocation, thus representing two oncogenic events from a single genomic lesion. BCL11B has been implicated as a core component of the SWI/SNF chromatin-remodeling complex, a key tumor suppressor in diverse human malignancies, thus SWI/SNF complex inactivation provides one potential mechanism to explain the pathogenic consequences of BCL11B in T-cell ALL.

PHF6 Mutations in T-Cell Acute Lymphoblastic Leukemia

T-cell ALL has a male predominance, suggesting the potential involvement of tumor suppressors on the X chromosome. Targeted mutational analysis of the X chromosome revealed one such candidate tumor suppressor, PHF6, which is nucleolus, ribosomal RNA (rRNA) promoter-associated protein that directly interacts with upstream binding factor (UBF) through its PHD1 domain and suppresses rRNA. Germline mutations of *PHF6* were first described in association with Borjeson-Forssman-Lehmann syndrome (OMIM 301900), which is associated with severe mental retardation and facial dysmorphisms but until recently had not been associated with T-cell ALL. Ferrando and colleagues identified somatic nonsense and frameshift mutations leading to loss of *PHF6* expression in 16% of pediatric and in 38% of adult T-cell ALL patient samples and which were associated with overexpression of the *TLX1* or *TLX3* oncogenic transcription factors. Recently, studies of murine models have demonstrated that the loss of *PHF6* is an early event in T-cell leukemogenesis and can accelerate the onset of Notch1-induced T-cell ALL, implicating a leukemia-initiating tumor suppressor role for *PHF6*. While the pathogenic consequences of *PHF6* inactivation in T-cell ALL remain an area of ongoing investigation, recent comprehensive sequencing studies by Ferrando and colleagues have demonstrated that inactivation of *PHF6* induces a transcriptional program that increases the self-renewal capacity of HSCs. Additionally, the loss of *PHF6* has been shown to lead to increased chromatin accessibility of *MYC* target genes implicated in cell cycle control. Other work has also demonstrated a role for *PHF6* in cell proliferation with loss of *PHF6* causing arrest at the G_2/M checkpoint and increased DNA damage at the ribosomal locus. Thus, it is postulated that *PHF6* acts as a tumor suppressor with a regulatory role in rRNA synthesis and genome maintenance.

Ribosomal Protein Gene Mutations in T-Cell Acute Lymphoblastic Leukemia

Mutations in ribosomal proteins that lead to impaired ribosome biogenesis and function are well characterized in disorders of normal hematopoiesis, such as Diamond-Blackfan anemia, and in 5q− myelodysplastic syndrome. Using whole-exome sequencing, recurrent mutations in *RPL5* and *RPL10* have also been identified in pediatric T-cell ALL. Moreover, gene expression analysis of pediatric T-cell ALL samples has identified monoallelic focal deletions of *RPL22*, a ribosomal gene that is required for the development of normal T-cell progenitors. While functional studies investigating ribosomal proteins in T-cell ALL have revealed a role in transformation and cell proliferation, the exact mechanism through which this may provide an advantage to the lymphoblasts remains unknown.

Hedgehog Pathway Activation in T-Cell Acute Lymphoblastic Leukemia

Mutations within the Hedgehog pathway, most commonly within *PTCH1*, have been identified in 16% of primary T-ALL cases and have been associated with resistance to induction chemotherapy. The Hedgehog signal transduction pathway stimulates growth and proliferation in multiple cell types during embryonic development, and loss-of-function mutations of *PTCH1*, a negative regulator of Hedgehog signaling, are known to result in aberrant Hedgehog pathway activation and are well-described driver oncogenic mutations initially described in association with Gorlin syndrome (OMIM #109400), a rare inherited disorder characterized by early-onset basal cell carcinoma and increase the risk of medulloblastoma. The Hedgehog pathway may play a role in normal and malignant T-cell development. Studies in human T-cell ALL cell lines have shown that the Hedgehog pathway mutations lead to aberrant ligand-independent activation of Hedgehog signaling and that Hedgehog pathway mutation are required for survival signaling in *PTCH1*-mutant T-ALL cells. Moreover, the disruption of *ptch1* accelerated the onset and increased the penetrance of *notch1*-induced T-cell ALL in a zebrafish model. While the mechanism by which Hedgehog activation leads to T-cell leukemogenesis and chemotherapy resistance is not well understood, human and murine studies have demonstrated a potential role for Hedgehog pathway inhibitors in *PTCH1*-mutant T-cell ALL.

Fanconi-*BRCA* Mutations in T-Cell Acute Lymphoblastic Leukemia

The Fanconi pathway plays a critical role in DNA repair, and mutations in Fanconi genes have been linked to the development of both sporadic and inherited cancers. Additionally, studies have demonstrated the development of T-cell lymphomas in BRCA2-deficient mice. Recent genomic analysis of childhood T-cell ALL has identified frequent loss of function mutations within the Fanconi-*BRCA* pathway. Interestingly, these cases retained expression of the wild-type allele, suggesting that partial inactivation of the Fanconi-*BRCA* pathway may cooperate with other genetic lesions in T-cell ALL transformation. BRCA2 haploinsufficiency revealed a gene expression profile consistent with activation of the DNA damage repair pathway and being hypersensitive to UV irradiation. Together, this suggests a potential role for targeted therapy with ATR inhibitors, which are in clinical testing in a wide spectrum of tumors.

Abnormalities of Leukemia Cell Ploidy

Abnormalities of chromosome number, which generally occur in the absence of specific chromosomal translocations, have important prognostic and biologic implications in childhood ALL.

Hyperdiploidy

Found in 25% to 30% of childhood ALL cases, high hyperdiploidy, defined as the presence of 51 to 65 chromosomes in the leukemic clone, is the most frequent in childhood ALL and, in general, associated with a favorable prognosis. High hyperdiploid ALL is characterized by nonrandom gain of chromosomes X, 4, 6, 10, 14, 17, 18, and 21; trisomies of chromosomes 4, 10, and 17 impart a particularly good prognosis. Genomic analyses have revealed that chromosomal gains are commonly early events, corroborating with other evidence that high hyperdiploidy is a genetic driver event during B-cell leukemogenesis and have demonstrated frequent involvement of the RTK-RAS-ERK pathway and histone modifiers in this subtype of B-cell ALL. High hyperdiploidy occurs more frequently in younger children than in adolescents and adults and is more common in B-ALL than T-ALL. The mechanisms accounting for the favorable outcome of patients with high hyperdiploid ALL remain unknown but may reflect increased sensitivity to antimetabolite therapy and a greater propensity to undergo apoptosis. Mutations in genes of the RTK/*RAS* pathway are frequently observed in high hyperdiploid ALL, and *FLT3* mutations/overexpression have also been observed in these patients.

Near triploid (68 to 80 chromosomes) and near tetraploid ALL (>80 chromosomes) are much less common and appear to be biologically distinct from high hyperdiploidy (51 to 65 chromosomes). The prognostic significance of these subtypes is less well characterized. Near tetraploidy is frequently associated with *ETV6-RUNX1* fusions.

Hypodiploidy

In marked contrast to the favorable outcomes associated with high hyperdiploidy, the occurrence of hypodiploidy (<45 chromosomes), which is much less common, carries a poor prognosis, especially in cases with less than 40 chromosomes. A large-scale genomic study has revealed that hypodiploid ALL comprises two molecularly distinct biologic entities. Near-haploid ALL (24 to 31 chromosomes) commonly harbors activating mutations in the *RAS* pathway, with activating mutations of *RAS* genes or loss-of-function mutations of its negative regulator *NF1* being particularly common. By contrast, low hypodiploid ALL (32 to 39 chromosomes) has an exceptionally high frequency of p53 mutations, which are otherwise very rare in ALL. Strikingly, nearly half of the p53 mutations observed in low hypodiploid ALL appear to be germline. A subgroup of patients has also recently been identified with so-called "masked hypodiploidy," in which the hypodiploid clone doubles, thus appearing by karyotype to have 50 to 78 chromosomes. Careful evaluation of the DNA index fluorescence in situ hybridization (FISH), and karyotype, as well as the evaluation of co-occurring mutations can be useful in identifying cases of masked hypodiploidy, which is essential for risk stratification. Despite the differences in underlying genetic alterations, both near-haploid and low-hypodiploid ALL are associated with activation of *RAS* and *PI3K* signaling pathways, and preclinical data support the potential therapeutic utility of PI3K pathway inhibitors for these patients. Moreover, preclinical studies of hypodiploid ALL have demonstrated a dependence on *BCL-2*, suggesting that the selective BH3 mimetic, venetoclax, may have therapeutic utility in hypodiploid B-cell ALL. In vivo studies of venetoclax have demonstrated increased survival in patient-derived xenograft models of hypodiploid B-cell ALL.

Polysomy 21

Gains of additional copies of chromosome 21 are the most common somatic aneuploidy in B-cell ALL, and patients with germline trisomy 21 (Down syndrome) are at increased risk of this disease. Additionally, chromosome 21 is never lost in ALL cases with hypodiploidy, highlighting the role of additional copies of chromosome 21 in ALL pathobiology. Until recently, the molecular mechanisms linking trisomy 21 to B-cell leukemogenesis were unknown. Recent work with a murine model harboring triplication of 31 genes that are orthologous to the segment of chromosome 21q22 revealed that chromosome 21q22 triplication leads to aberrant self-renewal and differentiation arrest of B-cell progenitors. Moreover, chromosome 21q22 triplication accelerates the onset of B-ALL induced by either *BCR-ABL1* or the combination of *CRLF2* and activated *JAK2*. Polysomy 21 was found to induce loss of the repressive histone mark H3K27 trimethylation, indicating suppression of the activity of the PRC2. This effect was mediated, at least in part, by overexpression of *HMGN1*, a gene that encodes a histone remodeling protein and is located on the triplicated region of chromosome 21q22. These findings thus formally prove that polysomy 21 is oncogenic in the B-cell lineage and provide a molecular mechanism linking this chromosomal lesion to B-cell pathobiology.

In addition to whole-chromosome 21 gains, 1% to 2% of B-cell ALL cases are characterized by amplification of material from an approximately 5 Mbp region of chromosome 21 that includes *RUNX1*, the so-called intra-chromosomal amplification of chromosome 21 (iAMP21). Interestingly, iAMP21 is 2,700 fold more common in individuals with a germline Robertsonian translocation involving chromosomes 15 and 21. These translocations result in the fusion of the long arms of chromosomes 15 and 21 into a single chromosome. Both of these chromosomes are acrocentric with little genetic material on their short arms; thus, little genetic material is lost and heterozygous carriers are phenotypically normal. Whole-genome sequencing analysis of ALL cases with iAMP21 has revealed highly complex structural and copy number rearrangements within the amplified region. Interestingly, reconstruction of the evolution of this lesion strongly suggests that the initiating event for this lesion is chromothripsis, or the shattering of a chromosome in a single catastrophic event, followed by additional amplification via breakage-fusion-bridge cycles. These data strongly suggest that the abnormal structure of the Robertsonian chromosome predisposes it to focal genomic instability involving chromosome 21, possibly because it is prone to mitotic segregation errors, thus providing a potential mechanism linking germline chromosome 21 Robertsonian translocations and iAMP21. Children with i*Amp*21 ALL are often older at presentation with a mean age of 9 years and have a low white blood cell count. Several studies have demonstrated an increased risk of relapse with this chromosomal aberration; however, more recent studies have shown improved outcomes with the intensification of therapy for patients with *iAmp21*.

GERMLINE PREDISPOSITION IN ACUTE LYMPHOBLASTIC LEUKEMIA

While somatically acquired genomic alterations have provided significant insight into the pathobiology of ALL, the importance of inherited genetic variation, termed germline variants, on ALL susceptibility has more recently been uncovered. ALL most commonly develops between the ages of 2 and 5 years of age, and acquired genomic alterations have been identified at birth. Together, this suggests there may be a strong association with inheritable risk factors. Recently, both rare variants associated with a high risk of development of ALL and common variants identified in genome-wide association studies (GWAS) that are associated with a more modest risk of ALL have been identified.

Susceptibility Loci in Acute Lymphoblastic Leukemia

GWAS in childhood B-cell ALL have identified several susceptibility loci, including *ARID5B*, *IKZF1*, *GATA3*, *PIP4K2A*, *CEBPE*, *BMI1*, *CDKN2A, BAK1*, and *IGF2BP1*. The population frequency of these common variants differs significantly by ancestry and may account for racial differences in the development of ALL. Interestingly, many of the risk loci identified by GWAS undergo frequent somatic mutation in ALL, such as deletions of *IKZF1* and loss of *CDKN2A*, both described elsewhere in this chapter. There does not appear to be cosegregation, however, suggesting that inherited common risk alleles and somatically acquired mutations function independently. Furthermore, while there is speculation that these risk alleles may alter normal hematopoiesis (*ARID5B*, *IKZF1*, *GATA3*, *CEBPE*, *BMI1*, *BAK1*) and/or cell cycle regulatory control (*CDKN2A* and *IGF2BP1*) based on the function of somatic mutations within these genes, the molecular mechanisms by which these common variants increase the risk for the development of ALL remain largely unknown, highlighting the need for functional studies to further elucidate the inherited basis of B-ALL.

Recently, a large GWAS performed in childhood T-cell ALL revealed two susceptibility loci: *CDKN2A* and the novel risk locus, *USP7*. The variants identified in *CDKN2A* overlap with those identified in B-cell ALL. As was seen in B-cell ALL, somatic mutations of both *CDKN2A* and *USP7* frequently occur in T-cell ALL. Further analysis of the functional consequence of the identified *USP7* variants suggests that they impair USP7 function, similar albeit to a lesser extent than somatic mutations. Further studies are needed, however, to better understand the exact mechanism by which common variation of *USP7* influences T-cell leukemogenesis.

Rare Variation in Familial Acute Lymphoblastic Leukemia

Through kindred studies, inherited, rare variants have been identified over the past decade in association with familial predisposition to ALL.

Inherited *ETV6* Loss of Function Mutations in B-Cell Acute Lymphoblastic Leukemia

ETV6 is a transcription factor important in the regulation of normal hematopoiesis, and alterations in *ETV6*, including single nucleotide variants, copy number loss, and chromosomal rearrangements, are among the most common genetic lesions in B-cell ALL. Recently, *ETV6* has been identified in association with familial thrombocytopenia and increased risk for development of leukemia, particularly B-cell ALL, constituting a novel leukemia predisposition syndrome that accounts for approximately 1% of ALL cases. Functional analysis of identified germline variants identified two classes of mutations: damaging mutations, which were predominately restricted to the ETS domain, and WT-like mutations that did not show a preference for the ETS domain. The damaging germline variants resulted in reduced DNA binding and impaired transcriptional repressor activity. Importantly, these variants retained their ability to dimerize and function in a dominant-negative manner by sequestering wildtype ETV6 protein to the cytoplasm. In contrast, the WT-like variants retained normal protein function. Genomic and transcriptomic analysis demonstrated that the germline *ETV6*-mutated cases clustered with hyperdiploid ALL, characterized by secondary somatic mutations in the RAS pathway, or diploid ALL (clustering with ETV6-RUNX1 cases) with recurrent somatic *PAX5* alterations and copy number loss of *ETV6*. Similar to other genes that predispose to leukemia, the location of the germline variant and secondary somatic mutations appear to determine both the penetrance and molecular classification of disease in *ETV6* leukemia predisposition syndrome.

Inherited *PAX5* Mutations in B-Cell Acute Lymphoblastic Leukemia

Somatic mutations in the lymphoid transcription factor, *PAX5*, have long been a hallmark of B-cell ALL development (as described earlier). More recently, however, a recurrent germline variant of PAX5, p.Gly183Ser, has been implicated in ALL development. This missense variant, identified in three unrelated kindreds, appears to cosegregate with deletion of *CDKN2A* on chromosome 9p and loss of the wildtype *PAX5* allele, suggesting that this mutation leads to loss of normal protein function. In contrast to other ALL predisposition syndromes, all affected individuals within the identified kindreds develop B-cell ALL, suggesting an autosomal dominant inheritance pattern. Further comprehensive sequencing studies of *PAX5* in B-cell ALL should be pursued to define the role that *PAX5* may play in ALL susceptibility.

Inherited Alterations of *IKZF1* in B-Cell Acute Lymphoblastic Leukemia

IKZF1 is a master transcriptional regulator critical for lymphoid development, and somatic alterations, particularly deletions, of *IKZF1* are well described in B-cell ALL. More recently, rare germline alterations of the N-terminal DNA binding domain of *IKZF1* have been described in association with inherited immunodeficiencies and risk for development of B-cell ALL. Further genomic analysis of sporadic B-cell ALL identified germline alterations in *IKZF1* in 0.9% of B-cell ALL cases sequenced. These unique alterations included missense, nonsense, and frameshift mutations and in contrast to those identified in association with immunodeficiencies did not preferentially localize to the DNA binding domain and had minimal effect on transcriptional repressor activity. In fact, functional assays demonstrated that these mutations had variable effects on IKZF1 dimerization, localization, cell adhesion, and drug sensitivity.

Germline *TP53* Mutations in Hypodiploid B-Cell Acute Lymphoblastic Leukemia

Germline variation in *TP53*, the genetic basis for Li-Fraumeni syndrome, has been reported in association with childhood hypodiploid ALL and is thought to confer an inferior prognosis. A study of 3801 children with newly diagnosed ALL identified rare loss of function variants largely restricted to a critical DNA binding domain, consistent with what has been described with somatic *TP53* mutations in ALL. Functional in vitro assays identified pathogenic variants resulting in loss of transcriptional activation. The molecular basis for cosegregation of *TP53* germline variants and hypodiploid ALL remains unknown. There is speculation that impaired p53-mediated DNA damage repair may lead to global genomic instability, resulting in aneuploidy; however, aneuploidy is not enriched in other Li-Fraumeni–associated cancers. Alternatively, this aneuploidy may be a function of the interaction between *TP53* germline mutations and other somatic alterations in hypodiploid ALL. The overall inferior clinical outcome associated with *TP53*-mutated hypodiploid ALL is likely related to chemotherapy resistance, in part mediated by impaired DNA damage response. Additionally, patients with *TP53* germline mutations have a high rate of treatment-related secondary cancers, which further impacts clinical outcome in this group of patients.

While rare germline variants account for only a very small proportion of ALL cases, the recognition of inherited susceptibility to ALL has become increasingly important, as it can have a profound clinical impact on screening, disease surveillance, and treatment. Moreover, further studies and advancements in the field of ALL genetic predisposition will no doubt provide critical insights into the molecular basis of ALL.

CHEMOTHERAPY RESISTANCE MECHANISMS AND NOVEL THERAPEUTIC TARGETS

Apoptosis Resistance and Mitochondrial Apoptosis

Despite the clinical application of conventional cytotoxic chemotherapy for more than 50 years, the molecular determinants of chemotherapy response have received relatively little attention. Recent work has implicated a major role in resistance to cell death through the mitochondrial pathway. The mitochondrial pathway of apoptosis is regulated by the relative activity of pro- and antiapoptotic BCL2 family members, which converge at the mitochondrial outer membrane. When survival signals predominate, the BAX and BAX effector proteins are in an inactive conformation. However, induction of mitochondrial apoptosis culminates in the activation of BAX and BAK, which oligomerize to form pores in the mitochondrial outer membrane. This step triggers mitochondrial depolarization, cytochrome c release, and subsequent caspase activation and is generally considered the point of irreversible commitment to cell death. Recent work using an assay to measure the ability of a fixed proapoptotic stimulus to trigger mitochondrial depolarization has revealed that a tumor cell's sensitivity to mitochondrial apoptosis is a major determinant of chemotherapy response. Indeed, resistance to mitochondrial apoptosis can predict the clinical outcome for patients with a wide range of tumors, including ALL. Investigation of the dependence of ALL cells on specific antiapoptotic factors revealed that most cases of B-cell ALL and of ETP ALL are dependent on the antiapoptotic BCL2 protein, whereas "typical" T-cell ALL cases are most often dependent on a distinct antiapoptotic protein, BCL-XL. Small-molecule inhibitors of both of these proteins have been developed and demonstrate promising activity in preclinical models.

NT5C2 Nucleosidase Gene Mutations in Acute Lymphoblastic Leukemia

Genomic analyses of relapsed ALL clinical specimens have revealed activating point mutations in the cytosolic 5′-nucleotidase II gene (*NT5C2*), occurring in approximately 20% of relapsed T-cell ALL cases and in 3% of relapsed B-cell ALL. *NT5C2* encodes a 5′-nucleotidase enzyme that metabolizes and inactivates nucleoside analog chemotherapeutics, including 6-mercaptopurine and 6-thioguanine. Point mutations within *NT5C2* lead to increased enzyme activity in vitro, and their expression is sufficient to induce resistance to 6-mercaptopurine and 6-thioguanine in ALL cells. Patients with *NT5C2* mutations presented with early relapse (occurring within 36 months of achieving remission) and had a uniformly poor prognosis.

Pharmacologic PP2A Activation in T-Cell Acute Lymphoblastic Leukemia

A small-molecule screen in a zebrafish model of MYC-induced T-cell ALL revealed that perphenazine has activity against zebrafish and human T-cell ALL. Perphenazine is an FDA-approved antipsychotic best known as an inhibitor of dopaminergic signaling, but its anti-leukemic activity could not be explained by any of its known molecular targets. Using a mass spectrometry-based approach, PP2A was identified as a novel target of perphenazine. Perphenazine was found to bind and activate the phosphatase activity of PP2A, leading to dephosphorylation and inactivation of several oncoproteins with well-known roles in leukemogenesis, including MYC and AKT. Despite its key role as a tumor suppressor, PP2A inactivating mutations have not been described as a recurrent event in T-cell pathobiology. This is likely because each subunit of PP2A is encoded by multiple redundant genes, making it easier for a tumor cell to inactivate PP2A function by overexpression of a negative regulator, such as the *TLX1* oncogene. Although the dopaminergic neurotoxicity of perphenazine is an obstacle to immediate clinical translation of these findings, the development of more potent and specific PP2A activators could have important therapeutic applications for patients with T-cell ALL and other cancers driven by hyper-phosphorylated PP2A substrates.

FUTURE DIRECTIONS

The immediate applications of the emerging molecular information include a refinement of risk classification schemes to emphasize the roles of somatically acquired genetic abnormalities that carry a defined prognosis and likelihood of therapeutic failure. Currently, patients are assigned to treatment according to their initial clinical features and, increasingly, the genetic and biologic properties of their leukemic cells. We are now in a position to view ALL as a group of heterogeneous diseases defined by discrete molecular lesions. As these lesions have been systematically analyzed in larger numbers of patients, it has been possible to devise new classification schemes for ALL that reflect prognosis with precision. The development of new drugs based on the molecular biology of ALL, whose promise is highlighted by the early success of imatinib in BCR–ABL1–positive ALL, is clearly a priority for the future and will likely take the form of compounds developed to specifically interfere with oncoprotein function and other pro-survival mechanisms specific to each patient's leukemic blasts. Additionally, the discovery that enzymes such as kinases and histone methyltransferases play important roles in ALL pathogenesis has provided new opportunities for targeted drug development. With these advances in the understanding of the pathobiology of various ALL subsets, there is potential to improve outcomes through clinical trials coordinated on a nationwide or even worldwide scale that focus on patients with ALL whose lymphoblasts harbor specific genetic abnormalities.

CHAPTER 67

CLINICAL MANIFESTATIONS AND TREATMENT OF CHILDHOOD ACUTE LYMPHOBLASTIC LEUKEMIA

Rayne H. Rouce and Rachel E. Rau

Serial risk-directed clinical trials have optimized the combination of chemotherapeutic agents and, along with advances in supportive care, have led to current cure rates of childhood acute lymphoblastic leukemia (ALL) exceeding 85% compared with those of less than 10% in the 1960s.[1] However, because ALL is the most common cancer in children, relapsed ALL remains a leading cause of death from disease in this age group. Over the last two decades, minimal residual disease (MRD) has become the most important determinant in risk stratification. Prophylactic cranial irradiation has been successfully omitted from virtually all patients in several frontline protocols, and the Abelson (ABL) tyrosine kinase inhibitors (TKIs) imatinib and dasatinib have revolutionized the treatment of patients with Philadelphia chromosome (Ph)-positive ALL. Significant advances in biotechnology, such as next-generation sequencing (NGS), have led to a deeper understanding of the molecular pathways involved in ALL, which in turn helped identify new ALL subtypes and their driver mutations.[1] Precision medicine ALL strategies based on inherited and leukemia-specific genomic features, host pharmacogenomics, and targeted molecular and immunologic treatment approaches are increasingly implemented to improve cure rates and reduce toxicity. The remarkable success of bispecific T-cell engagers and chimeric antigen receptor modified T cells (CAR-T cells) targeting CD19, once considered only as treatment of relapsed or refractory B-ALL, has led to their testing in upfront clinical trials, while changing the way practitioners assess allogeneic hematopoietic stem cell transplant (allo-HSCT).

EPIDEMIOLOGY

ALL accounts for approximately 75% of all cases of childhood leukemia, and is the most common pediatric cancer, representing 23% of cancer diagnoses among children younger than 15 years of age. About 3600 children and adolescents are diagnosed with ALL each year in the United States, with an annual rate of 30 to 40 per million. The peak incidence of ALL occurs around 3 to 5 years of age. This young age peak historically has been associated with major periods of industrialization in many countries, suggesting a causative role for environmental changes. ALL, especially T-cell subtype, occurs more frequently in boys than in girls.[1]

Certain inherited genetic and acquired factors are associated with the development of ALL, but most patients have no recognized risk factors. Children with constitutional trisomy 21 (Down syndrome) are up to 15 times more likely to develop leukemia than children without Down syndrome. Genetic instability and DNA repair disorders (e.g., Bloom syndrome, ataxia-telangiectasia, Fanconi anemia) are also associated with an increased risk of developing ALL.[2] Among identical twins, if one is diagnosed with ALL during the first year of life, the risk that the other twin will develop ALL is over 70%, approaching 100% in twins with a single monochorionic placenta. The extraordinarily high concordance rate in monozygotic infant twins compared with dizygotic infant twins or non-twinned siblings results from the metastasis of leukemic cells from one twin to the other through shared placental circulation. Highest in infancy, this risk diminishes with increasing age. If the first twin develops ALL by 5 to 7 years of age, the risk to the second twin is approximately twice that in the general population, regardless of zygosity.[3] After the age of 7 years, the risk to the unaffected twin is similar to that for persons in the general population. The majority of infants with ALL have a chromosome translocation that results in the fusion of the *KMT2A* (formerly *MLL*) gene at 11q23 with a variety of partner genes, the most common of which in B-ALL is *AF4*. Identical twin infant pairs with concordant ALL share the same acquired *KMT2A* gene rearrangements.

Several genetic, dietary, and environmental factors have been proposed to modify the risk of leukemia initiation. Children with various congenital immunodeficiency diseases, including Wiskott-Aldrich syndrome, congenital hypogammaglobulinemia, and ataxia-telangiectasia, have an increased risk of developing lymphoid malignancies, as do patients undergoing chronic treatment with immunosuppressive drugs. The loss of cellular immune surveillance capability for tumor antigens and the inability to self-regulate lymphoproliferative processes may contribute to malignant transformation in these patients. Absence of exposure to common infections in the first year of life is associated with a higher risk of developing *ETV6-RUNX1*–positive or hyperdiploid ALL (>50 chromosomes) in older children. A possible explanation is that in the absence of infection-driven modulation of the naive immune network in infants, subsequent infectious exposures could result in a highly dysregulated response to infections in older children contributing to leukemogenesis. Exposure to ionizing radiation and certain toxic chemicals could also facilitate the development of acute leukemia. Other evidence linking most environmental exposures to risk of childhood ALL has largely been inconsistent. Causation pathways are likely to be multifactorial and it is probable that the risk of ALL from environmental exposure is influenced by germline genetic variations through the co-inheritance of multiple low-risk variants.

PATHOBIOLOGY

Acute leukemias comprise a group of clonal disorders of maturation at an early phase of hematopoietic differentiation. ALL subtypes are a heterogeneous group of malignancies with distinctive immunophenotype and molecular pathogenesis that result in varying clinical characteristics and response to therapy. Accurate pathobiologic diagnosis is not only important for prognostic stratification, but can also help define patient-specific therapeutic approaches.[1]

Lymphoblastic leukemias can arise from either B- or T-cell mutant hematopoietic progenitor cells capable of indefinite self-renewal. T-cell ALL can be classified into several distinct genetic subgroups that correspond to specific T-cell development stages and is frequently associated with translocations of T-cell receptor genes on chromosome 14q11 or 7q34 with other gene partners. Early T-cell precursor (ETP) ALL comprises 12% to 15% of T-ALL and is characterized by immature genetic and immunophenotypic features (CD1a-negative, CD8-negative, and CD5-weak and the co-expression of stem-cell or myeloid markers), and gene expression reminiscent of double-negative 1 thymocyte that retains the ability to differentiate into both T-cell and myeloid, but not B-cell lineages.[4] The discovery of its mutational spectrum recapitulated that of acute myeloid leukemia (AML) by whole genome sequencing (see discussion in Genomics of ALL) and global transcription profile similar to that of normal hematopoietic stem cells, and granulocyte macrophage precursors suggest that this subtype of leukemia is a stem-cell leukemia.[4] Most B-lineage leukemias are early precursor B cells, expressing CD19 and CD10 (or cALLa, the common acute leukemia antigen) but lacking surface or cytoplasmic immunoglobulin. The mature B-cell ALL, or Burkitt cell leukemia, is stratified separately and not included in this chapter.

GENOMICS OF ACUTE LYMPHOBLASTIC LEUKEMIA

Most cases of ALL harbor driver genetic aberrations. In B-ALL in particular, a number of recurrent structural chromosomal anomalies have been identified that are of pathogenic and prognostic importance. Recent advances in global genome analysis have enabled the identification of recurring alterations in genes and pathways with key roles in cell growth and tumorigenesis. The identification of such lesions may help further refine risk stratification and could represent targetable genetic vulnerabilities.

B-Acute Lymphoblastic Leukemia Genomics

Chromosomal aneuploidy is common in B-ALL. Hyperdiploidy (modal chromosome number 51 to 65 or DNA index of >1.16) is present in 20% to 25% of pediatric patients with B-ALL, most commonly in younger children with decreasing frequency with age. Hyperdiploidy is associated with a more favorable outcome and is incorporated into the risk stratification algorithm of several childhood cancer consortia worldwide. Studies from the Pediatric Oncology Group (POG) and subsequently the Children's Oncology Group (COG) have found that patients with trisomies of chromosomes 4 and 10 (double trisomies, DT) in particular (with or without meeting the definition of hyperdiploidy) have excellent outcomes with standard therapy, thus the COG incorporates DT as a favorable cytogenetic lesion in its risk stratification.[5]

Hypodiploidy (modal chromosome number <44 or DNA index of <0.81) is a relatively rare (1% to 2%) cytogenetic lesion associated with a particularly poor outcome in B-ALL. While data based on small numbers suggests patients with hypodiploidy who clear bone marrow (BM) MRD by the end of induction therapy have reasonably good outcomes with chemotherapy alone, analysis of a larger COG cohort revealed the outcomes were overall dismal and not improved by HSCT in first complete response (CR).[6] Thus, there is a dire need for novel therapeutic options for patients with hypodiploidy B-ALL.

Chromosomal translocations are also prevalent in B-ALL, a number of which have prognostic importance. Fusion of the *ETV6* and *RUNX1* genes by translocation t(12;21)(p12;q22) occurs in 20% to 25% of childhood B-ALL, and is associated with favorable outcome. Conversely, rearrangements of *KMT2A* on chromosome 11q23 are associated with poor prognosis. *KMT2A* rearrangements drive approximately 80% of infant B-ALL, and *KMT2A*r infant ALL is a particularly poor prognosis disease. *KMT2A* rearrangements are also found in 3% to 5% of older children with B-ALL, and while associated with increased MRD and inferior outcomes, the risk of relapse can largely be mitigated with intensification of chemotherapy.

Another recurrent structural chromosomal lesion conferring an increased relapse risk is intrachromosomal amplification of chromosome 21 (iAMP21) which is present in 1% to 3% of pediatric B-ALL cases. Similar to *KMT2A* rearrangements, outcomes are greatly improved with appropriate intensification of chemotherapy.[7] The *TCF3-HLF* fusion gene results from another, rare (<1%) translocation in B-ALL, t(17;19). B-ALL patients with *TCF3-HLF* fusions characteristically present with coagulopathy and hypercalcemia and have a dismal prognosis, thus warranting novel therapies and consideration of HSCT in first CR.

The t(9;22) Philadelphia chromosome (Ph+) is another recurrent and well-characterized genomic driver of B-ALL. This translocation results in the *BCR-ABL1* fusion gene. A number of potent and specific TKIs targeting *BCR-ABL1* such as imatinib and dasatinib have been developed, and their continuous administration in combination with standard ALL chemotherapy has dramatically improved the outcome of Ph+ B-ALL.[8]

In more recent years, gene expression studies of large B-ALL cohorts identified a subset of Ph-negative patients characterized by a gene expression profile highly similar to Ph+ B-ALL, subsequently designated Ph-like B-ALL (or *BCR-ABL1*-like) B-ALL. Whereas Ph+ B-ALL steadily increases with age, the incidence of Ph-like disease peaks in young adulthood. In B-ALL ~10% of children under 10 years, ~20% of adolescents, and greater than 30% of young adults have Ph-like disease with rates then decreasing with increasing age. Ph-like B-ALL is associated with poor prognosis, particularly in the AYA (adolescent and young adult) population. B-ALL patients of Hispanic ethnicity and Native American genetic ancestry have significantly higher rates of Ph-like disease and an association has been identified between the risk of Ph-like B-ALL and specific germline polymorphisms of *GATA3*.[9] While Ph-like B-ALL lacks the BCR-ABL1 kinase fusions, a number of lesions driving Ph-like B ALL have been identified via seminal genomic studies. The identified causative lesions are characterized by the activation of a number of different kinase signaling pathways.[10] Many of the activated kinase pathways can be selectively inhibited by targeted small molecule TKIs, thus providing a possible approach to improve the historically inferior outcomes of affected patients.

The most common subsets of Ph-like ALL are those with aberrantly increased expression of the gene, *cytokine receptor-like factor 2* (*CRLF2*) secondary to fusion with either *IGH* or *P2RY8*. Thymic stromal lymphopoietin receptor (TSLPR) is the cell surface receptor protein encoded by *CRLF2*. As a cell surface protein, TSLPR is readily detected by flow cytometry. Thus, cell surface expression of TSLPR on diagnostic flow cytometry is suggestive of Ph-like disease with a driving *CRLF2* fusion, though confirmatory testing by fluorescence in situ hybridization (FISH) is required to confirm the diagnosis. The signaling pathway responsible for the Ph-like gene expression signature in *CRLF2*-rearranged B-ALL is the pro-proliferative, pro-survival, anti-apoptotic Janus kinase/signal transducers and activators of transcription (JAK)/STAT) pathway. TSLPR forms a heterodimeric cell surface receptor with IL7 receptor α (IL7Rα) which activates the JAK/STAT signaling pathway when bound by ligand. Overexpression of *CRLF2* in Ph-like B-ALL results in constitutive JAK/STAT signaling hyperactivation. *CRLF2* rearranged B-ALL is also characterized by frequent activating *JAK1/2* mutations, highlighting the critical role of JAK signaling in disease pathogenesis. *CRLF2* alterations are enriched in B-ALL patients of Hispanic ethnicity and occur in approximately 50% of the B-ALL cases in children with Down syndrome.

Another, less frequent subset of Ph-like B-ALL with aberrant JAK/STAT activation are those with rearrangements of the erythropoietin receptor gene (*EPOR*) that produce a truncated protein lacking the negative regulatory domain. Other, rare, JAK/STAT activating lesions are recurrently identified in Ph-like B-ALL, including *IL7R* insertion or deletions, fusions of *JAK2*, and SH2B3 mutations/deletions.[10] As JAK/STAT activation drives a large subset of Ph-like B-ALL, ongoing trials are testing if the JAK1/2 inhibitor, ruxolitinib, in combination with standard chemotherapy will be tolerable and efficacious for the treatment of JAK-activated Ph-like B-ALL (NCT02723994, NCT03117751, NCT02420717).

Another 3% to 5% of pediatric B-ALL cases have kinase fusions resulting in constitutive activation of ABL-class kinases including, *ABL1/2*, *PDGFRA/B*, *CSF1R*, and *LYN*. ABL-class Ph-like disease may be effectively targeted by ABL kinase TKIs such as imatinib and dasatinib. The combination of ABL TKIs and chemotherapy is being explored for the treatment of ABL-class Ph-like disease (NCT02883049, NCT03117751, and NCT02420717). Rarely, lesions of other targetable activating signaling kinases such as *FLT3, FGFR1*, and *NTRK3* drive Ph-like A-ALL, suggesting the possibility to improve outcome with kinase inhibition.

The era of genome sequencing has essentially defined the landscape of genetic lesions driving B-ALL.[11] Recent work has uncovered recurrent genomic lesions in pediatric B-ALL characterized by distinct gene expression programs and clinical characteristics, of potential prognostic and therapeutic relevance. These include cases with combined deregulation of *DUX4*, a homeobox transcription factor, and *ERG*, a member of the erythroblast transforming-specific (ETS) transcription factor family (~7%); rearrangement of the zinc-finger protein 384 gene (*ZNF384*) (~4% to 5%); and monocyte enhancer factor D2 (*MEF2D*) rearrangements (~3% to 4%). *MEF2D*-rearrangements are more common in older children, whereas *ZNF384* rearrangements are enriched in younger B-ALL cases and tend to have weak CD10 expression and variable expression of myeloid and stem markers on immunophenotyping and gene expression analyses. *DUX4-ERG* dysregulated B-ALL has been associated with a favorable prognosis, and small studies suggest *MEF2D*-rearranged B-ALL may be associated with inferior outcomes. In B-ALL, *MEF2D* has multiple fusion partners, but all MEF2D fusions all are characterized by a gene expression profile with overexpression of *HDAC9* which is a known MEF2D target. Thus, inhibition of HDACs may represent a viable therapeutic adjuvant for the treatment of affected individuals. Although no significant difference in outcome was found in patients with *ZNF384* rearranged B-ALL as a whole, ZNF384 has multiple potential fusion partners (*TCF3, EWS1, CREBBP*, and *EP300*) and outcomes may vary depending on the specific fusion. Patients with the *TCF3-ZNF384* fusions are relatively resistant to corticosteroids and carry an increased risk of relapse. Prospective studies of larger, uniformly treated patients harboring these novel fusions will be necessary to precisely define their prognostic impact with modern era therapy.

Recent genomic studies of large cohorts of B-ALL patients have identified a number of collaborating genetic lesions with biologic and potentially prognostic and therapeutic significance. A single nucleotide polymorphism (SNP) array demonstrated substantial differences in the frequency of copy number abnormality (CNA) among various ALL subtypes. *KMT2A*-rearranged cases had less than one CNA per case, suggesting that *KMT2A* fusions are potent oncogenes that requires very few cooperating lesions to induce leukemia transformation, especially in infants, while other subtypes such as *ETV6-RUNX1* and *BCR-ABL1* leukemias have over eight lesions per case. Such SNP array studies have identified recurrent deletion of several transcription factors critical to normal B-cell development including *PAX5*, *EBF1*, and *IKZF1*. While deletion of each of these genes likely contributes to the development of B-ALL, only *IKZF1* deletion appears to impact prognosis, with *IKZF1* deletions and mutations being associated with a poor prognosis.[12] Deletions or sequence mutation of the *IKZF1* are present in 10% to 20% of pediatric B-ALL patients and are enriched in high-risk subsets including over 80% of Ph-positive (*BCR-ABL1*–positive) B-ALL cases and is common in Ph-like ALL. *IKZF1* deletions are also common in DUX4/ERG dysregulated B-ALL, but in this context are not associated with a poor prognosis. Cooperative groups have attempted to incorporate *IKZF1* status into risk stratification. The Associazione Italiana Ematologia ed Oncologia Pediatrica-Berlin-Frankfurt-Muenster (AIEOP-BFM) ALL 2000 trial demonstrated that patients with *IKZF1* deletion with concomitant deletion of *CDKN2*A, *CKN2*B, *PAR1*, or *PAX5* without deletion of *ERG* (termed IKZF1^{plus}) had a significantly worse 5-year event-free survival (EFS) than those with *IKZF1* deletions without the IKZF1^{plus} status, and those without *IKZF1* deletions (53 ± 6% vs 79 ± 5% vs 87 ± 1%, respectively).[13]

Recent genome-wide association studies have identified germline polymorphic variants in several genes (including *ARID5B*, *CEBPE*, *GATA3*, *CDKN2*A, *BMI1-PIP4K2A*, and *IKZF1*) that are associated with an increased risk of ALL or specific ALL subtypes. Rare germline mutations in *PAX5* and *ETV6* are linked to familial ALL.[9] In addition to identifying common, low-penetrance susceptibility alleles, these data provide insights into disease causation by identifying risk variants annotating genes involved in transcriptional regulation and differentiation of B-cell progenitors.

T-Acute Lymphoblastic Leukemia Genomics

Unlike B-ALL, genomic classifiers are not widely used to risk stratify patients with T-ALL. However, some consortia are exploring possible integration of clinical features, MRD, and recurrent genomic lesions for refinement of risk-adapted therapy for T-ALL.[14]

T-ALL is characterized by a number of structural chromosomal lesions and genetic mutations. Translocation involving transcription factors and epigenetic regulators (e.g., *TAL1*, *TLX1*, *TLX*3, *KMT2A*, *MLLT10*) are common. Deletions of *CDKN2A/B* and *PTEN* and mutations of signaling pathway and epigenetic regulators are also recurrent in T-ALL.[11]

Additionally, over 70% of T-ALL patients have activating mutations of *NOTCH1*, which encodes a transmembrane receptor and critical regulator of normal T-cell development and another 20% have loss-of-function mutations of *FBXW7*, a ubiquitin ligase that negatively regulates NOTCH1. Given the frequency of NOTCH1 activating lesions in T-ALL, inhibition of NOTCH1 has been explored. Most notably, gamma secretase inhibitors (GSIs) which block the cleavage and release of the active intracellular component of NOTCH1 have been clinically tested, but demonstrated limited efficacy and excess rates of intolerable gastrointestinal toxicity.[15]

Early T-Cell Precursor Acute Lymphoblastic Leukemia Genomics

Early T-cell precursor or early thymic precursor (ETP) ALL is a distinct subtype of T-ALL characterized by a stem-progenitor cell gene expression signature and an immature immunophenotype. While the first descriptions of ETP ALL found and associated with poor outcome, more recent data indicates that with appropriate risk-adapted therapy based on MRD outcomes of patients with ETP ALL are the same as those with non-ETP T-ALL.[16]

Importantly, genomic profiling of ETP-ALL samples has identified several potentially targetable lesions. Most prominently, ETP-ALL is characterized by mutations of activated signaling including activating Ras-pathway and *FLT3* mutations as well as epigenetic regulator mutations.[4]

CLINICAL MANIFESTATIONS

Children with ALL present with nonspecific symptoms and signs reflecting the degree of disruption in BM function and the extent of extramedullary infiltration. The most common presenting symptoms are fever, fatigue, pallor, petechiae, bruising, bleeding from mucosal surfaces, and pain. Patients, especially young children, may present with bone pain, arthralgia, or refusal to walk due to leukemic infiltration of the bone or joint, or to expansion of the marrow cavity by leukemic cells (Table 67.1). The evolution of symptoms may proceed over a few days, weeks, or months. Less common presenting symptoms include headache, visual complaints, vomiting, respiratory distress, oliguria, and anuria. Occasionally, patients present with life-threatening infection or bleeding.

On physical examination, fever, pallor, petechiae, and ecchymoses may be present. The lymphoproliferative nature of the disease may be manifested as lymphadenopathy, splenomegaly, or hepatomegaly. Overt central nervous system (CNS) involvement is uncommon at presentation, but leukemic cells can be detected by screening lumbar puncture (Fig. 67.1A,B) in as many as 20% of children with ALL, especially those with high-risk disease who are asymptomatic at the time of the puncture. Papilledema, retinal hemorrhages, and cranial nerve palsies may be present. CNS involvement usually is restricted to leptomeninges, and parenchymal mass lesions are uncommon. Epidural spinal cord compression is a rare but serious presenting finding and requires immediate chemotherapy including high-dose glucocorticoid therapy. Laminectomy or radiotherapy is generally not necessary because leukemias are very sensitive to chemotherapy at diagnosis. Overt testicular involvement occurs in only 2% of boys and usually presents as painless, asymmetric enlargement that can be distinguished from hydrocele by ultrasonography (Fig. 67.1C,D). Less common presenting features include ocular involvement, subcutaneous nodules (leukemia cutis) (Fig. 67.1E,F), and enlarged salivary glands (Mikulicz syndrome). Approximately 55% of T-cell cases present with an anterior mediastinal mass. A bulky mediastinal mass can compress the great vessels and trachea, resulting in superior vena cava syndrome and respiratory distress. Patients with large mediastinal mass generally present with cough, dyspnea, orthopnea, dysphagia, stridor, cyanosis, facial edema, increased intracranial pressure, and sometimes syncope. When significant tracheal compression is present, general anesthesia should be avoided and procedures should be performed under local anesthesia. Immediate diagnosis and initiation of steroids and chemotherapy is essential to prevent respiratory failure. Lumbar puncture and intrathecal therapy can be delayed for a few days, allowing the relief of airway compression and decrease in circulating blasts, without compromising ultimate clinical outcome.

Clinical laboratory data often reveal a broad spectrum of abnormal findings. Various degrees of anemia and thrombocytopenia are usually present at diagnosis. The presenting leukocyte counts range widely from 0.1 to 1500 × 10^9/L. Leukemic blasts may not be appreciated morphologically in the peripheral blood smear in 10% of the patients. Approximately 45% of children have leukocyte counts less than 10 × 10^9/L, and 15% present with hyperleukocytosis (>100 × 10^9/L). Patients with hyperleukocytosis are at increased risk of CNS disease, tumor lysis syndrome, and leukostasis. Leukostasis may manifest as dyspnea, chest pain, alteration in mental status, cranial nerve palsies, or priapism. The majority of childhood ALL cases are B cell in derivation with approximately 12% to 15% of children with ALL having a T-cell immunophenotype. T-cell ALL usually occurs in patients older than 9 years of age with elevated leukocyte count, and is associated with CNS involvement. Coagulopathy, usually mild, can occur in T-cell ALL and is only rarely associated with severe bleeding. Elevated serum uric acid and lactate dehydrogenase levels are common in patients with a large leukemic cell burden. Patients with massive

TABLE 67.1 **Clinical Presentation of Acute Lymphoblastic Leukemia**

Symptoms/ Signs	Etiology	Management
Fever	Disease or infection	Always conduct fever work up and provide broad antimicrobial coverage until infectious etiology is ruled out
Fatigue, pallor	Anemia (ALL infiltrating bone marrow)	Packed red blood cell transfusion (slow if anemia is severe, avoid in hyperleukocytosis)
Petechiae, bruising, bleeding	Thrombocytopenia (ALL infiltrating bone marrow)	Transfuse with platelets
Pain	Leukemia infiltrating bones/joints, or expanding marrow cavity	Establish diagnosis and start chemotherapy
Respiratory distress/ superior vena cava syndrome	Mediastinal mass	Avoid sedation in presence of tracheal compression. Establish diagnosis as soon as possible and start chemotherapy

ALL, Acute lymphoblastic leukemia.

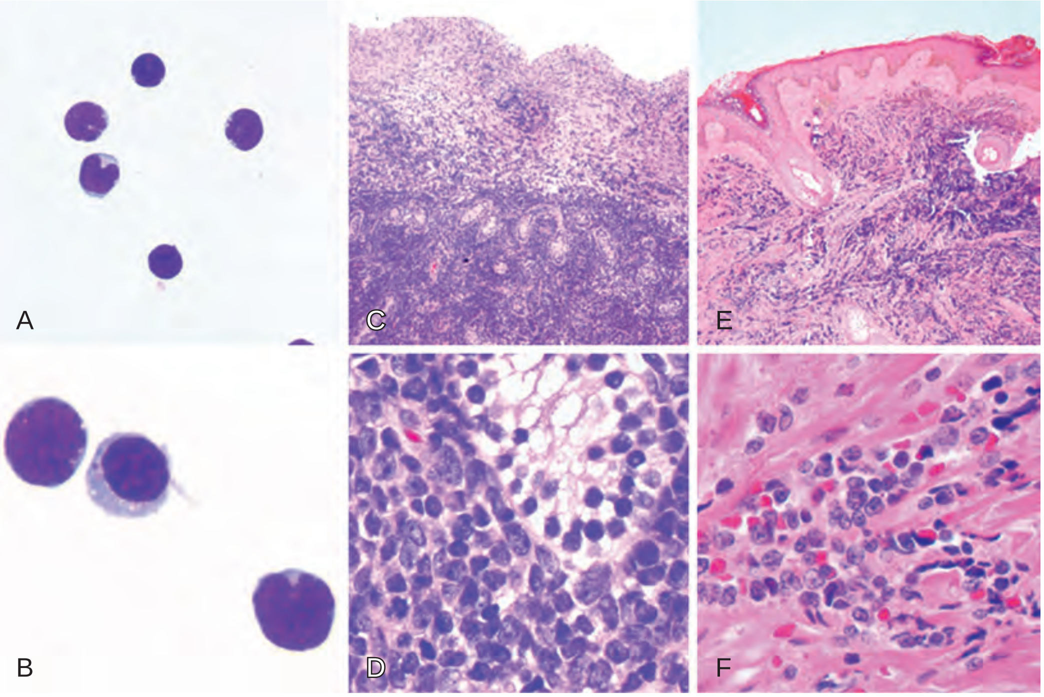

Figure 67.1 CENTRAL NERVOUS SYSTEM (CNS), TESTICULAR, AND SUBCUTANEOUS INVOLVEMENT IN CHILDHOOD ACUTE LYMPHOBLASTIC LEUKEMIA (ALL). CNS disease identified in the cerebrospinal fluid (CSF) by screening lumbar puncture at the time of diagnosis in a 12-year-old boy with high-risk precursor B-cell ALL. The total count of the CSF specimen was 6131/μL with 6076 white blood cells/μL and 98% blasts. (A, B) The cytospin preparation shows mostly blasts, slightly altered morphologically by the preparation. In (B), there is a small lymphocyte *(middle)* for comparison with the blasts. (C, D) Testicular disease noted at relapse in a 13-year-old boy with precursor B-cell ALL. Note the infiltrate of blasts in the parenchyma of the testes, surrounding the seminiferous tubules. Immunostaining (not shown) demonstrated that the blasts were $CD19^+$, $CD10^+$, and TdT^+. (E, F) Cutaneous disease at diagnosis. The patient was an 8-year-old boy with a scalp lesion for 2 months that was initially treated with antibiotics. (F) On biopsy there was much crush artifact, but deep in the specimen there was an infiltrate of blasts separating fibers shown to be B-cell lineage. Interestingly, the patient had a normal complete blood count, but bone marrow was packed with blasts that had a precursor B-cell phenotype and a hyperdiploid karyotype.

renal involvement can have increased levels of creatinine, urea nitrogen, uric acid, and phosphorus; intrathecal methotrexate should be delayed for a few days to avoid undue delay in methotrexate clearance resulting in systemic toxicity in these patients. Approximately 0.5% of patients have hypercalcemia at diagnosis, attributable to the release of parathyroid hormone–like protein from lymphoblasts and leukemic infiltration of bone; these patients tend to be in the older age group and present with low blast cell count, and this complication generally resolves rapidly with hydration and chemotherapy. As described above, the chromosomal rearrangement t(17;19), observed in less than 1% of precursor B-ALL, has been associated with hypercalcemia and coagulopathy. Liver dysfunction due to leukemic infiltration occurs in 10% to 20% of patients, is usually mild, and has no prognostic consequences. Because vincristine and daunorubicin are metabolized primarily through biliary excretion, modifications of the dosage of these agents are recommended if direct bilirubin level is elevated.

Abnormalities of the bone, such as metaphyseal banding, periosteal reactions, osteolysis, osteosclerosis, or osteopenia, can be demonstrated by radiographic studies in one-half of the patients, especially those with low presenting leukocyte counts. Routine bone surveillance is not necessary because these findings have no clinical or prognostic implication. Vertebral compression fracture that can be found in 2% of the cases in routine chest X-ray to detect mediastinal mass, is usually associated with low leukocyte count and hyperdiploidy (>50 chromosomes), and is not associated with adverse prognosis.

DIFFERENTIAL DIAGNOSIS

Children with ALL present with a variety of nonspecific symptoms that may mimic other conditions. Pancytopenia and fever are also presenting symptoms for aplastic anemia. Failure of a single cell line, as in transient erythroblastic anemia, idiopathic thrombocytopenic purpura, and congenital or acquired neutropenia, sometimes produces a clinical picture that is difficult to distinguish from ALL. Routine BM aspiration is not necessary for patients with severe thrombocytopenia and no other hematologic or physical evidence of leukemia. However, BM aspiration should be performed to exclude leukemia in patients who require glucocorticoid treatment. Children with infectious mononucleosis or other acute viral illnesses may present with fever, adenopathy, splenomegaly, lymphocytosis, or pancytopenia. Fever, arthralgia, or a limp may frequently be confused with juvenile rheumatoid arthritis, which can also be associated with anemia, leukocytosis, and mild splenomegaly. Children with prominent bone pain frequently have nearly normal blood counts, a finding that can contribute to a delay in diagnosis. Immunostains and molecular studies help differentiate ALL from AML and other small blue cell malignancies that invade the BM including neuroblastoma, rhabdomyosarcoma, Ewing sarcoma, and retinoblastoma. Infants may present with subcutaneous nodules (leukemia cutis) that look clinically like Langerhans cell histiocytosis.

PROGNOSIS

Contemporary regimens have abolished the prognostic impact of many clinical and biologic features, demonstrating that the single most important prognostic factor in childhood ALL is appropriate risk-directed therapy (Table 67.2). Accurate assessment of relapse hazard is an integral part of ALL therapy, so that only high-risk patients are treated aggressively, with less toxic therapy reserved for cases at lower risk of failure.

To facilitate comparison of treatment results among different clinical trials, participants in a 1993 workshop sponsored by the United States National Cancer Institute adopted a uniform risk classification based on age and presenting leukocyte count. Two-thirds of the patients who were 1 to 9 years old with precursor B-cell ALL and a leukocyte count less than 50×10^9/L were considered to be at standard risk of relapse, while the other third were classified as high risk. This prognostic value of the United States National Cancer Institute (NCI) risk classification is limited to B-ALL, and cannot be applied to T-cell ALL. Importantly, the prognostic impact of age and, to a lesser extent, leukocyte count may largely be due to their association with specific genetic abnormalities. For example, the overall poor prognosis of infants less than 12 months of age can be explained by the very high frequency of *MLL* rearrangements (70% to 80%) in this age group, and the overall favorable outcome of patients aged 1 to 9 years is related to the preponderance of cases (70%) with hyperdiploidy (>50 chromosomes) or *ETV6-RUNX1* fusion, both favorable genetic features. Thus, the most appropriate strategy incorporates clinical features including NCI risk status and presence or absence of extramedullary disease as well as genetic characteristics, and perhaps most importantly, early response to remission induction treatment, as determined by MRD level.

B-ALL, lacking immunoglobulin synthesis, is the most common form of acute leukemia in children, and can be further divided into several subtypes based on the stage of differentiation. The high-risk features previously ascribed to pre-B-ALL (presence of cytoplasmic IgM) are closely associated with the presence of the t(1;19) translocation with *E2A* (*TCF3*)*-PBX1* fusion. Prognostic distinctions among ALL immunophenotypes, including the negative prognostic impact once associated with T-cell ALL and pre-B-ALL with *E2A-PBX1* fusion, have been abolished by recent improvements in risk-directed treatment. Aberrant expression of myeloid-associated antigens has been observed with certain genetic subtypes. CD15, CD33, and CD65 are expressed in ALL cases with a rearranged *MLL* gene, and CD13 and CD33 are expressed in cases with the *ETV6-RUNX1* fusion. Once associated with a poor outcome in some studies, myeloid-associated antigen expression has no prognostic impact in contemporary risk-directed treatment programs.

As described in detail in the genomics of ALL sections above, B-ALL can be risk stratified on the basis of recurrent genetic lesions, with hyperdiploidy (modal chromosome number >50/cell) and *ETV6-RUNX1* fusions associated with favorable response to therapy and in general excellent prognosis. Conversely, hypodiploidy (modal chromosome number <44/cell), iAMP21, *KMT2A* rearrangement, and t(17;19) are consistently associated with poor response to therapy and increased risk of treatment failure and/or relapse. For *KMT2A*r in older children and iAMP21, this relapse risk can largely be overcome by appropriate intensification of therapy, whereas means to improve outcomes for those with hypodiploidy and t(17;19) have yet to be established. Additionally, Ph+ and Ph-like B-ALL is associated with poor outcome, but in Ph+ disease this has been greatly improved by incorporation of ABL-targeting TKIs and the hope is for similar improvement in outcome for Ph-like patients with targetable kinase fusions. While not universally incorporated into risk stratification, *IKZF1* status is used by some ALL groups. In T-ALL while tumor genetics are not yet routinely incorporated into risk stratification schemas, clinical evidence suggests *KMT2A*r may lead to worse outcomes in T-ALL.

Genetic features do not entirely account for treatment outcome and their prognostic impact also depends on the treatment efficacy. Interindividual variability in the pharmacokinetics and pharmacodynamics of many antileukemic agents also contributes to the heterogeneity in treatment response among patients with specific genetic abnormalities.

The degree of reduction of the leukemic cell clone early during remission induction therapy is determined by leukemic cell genetics, microenvironment, and host pharmacogenetics and pharmacodynamics, and has shown greater prognostic strength than any other individual biologic or host-related feature.[17,18] Measurements of MRD, by flow-cytometric detection of aberrant immunophenotypes or by polymerase chain reaction (PCR) of clonal antigen-receptor gene rearrangements and more recently by next generation deep sequencing, provides a level of sensitivity and specificity that cannot be attained by traditional morphologic assessment of early treatment response. Patients who achieve an immunologic or molecular remission, traditionally defined as leukemic involvement of less than 10^{-4} nucleated BM cells on completion of remission induction, have a much more favorable prognosis than do those who do not

TABLE 67.2 Prognostic Factors in Acute Lymphoblastic Leukemia

Factor	Prognosis	Clinical Application
Age		
<1 year	*KMT2A*r (70%–80% infants) poor outcome; *KMT2A*^{WT} same outcome as older children	*KMT2A*^{WT} do well on standard ALL therapy Potential role for proteasome inhibitors, histone deacetylase inhibitors, hypomethylating agents, BCL2 targeted agents, immunotherapy for *KMT2A*r
1–9 years	Lower (standard) risk	ALL biology may change risk
>9 years	Higher risk	ALL biology may change risk
WBC		
$<50 \times 10^9$/L	Lower (standard) risk	ALL biology may change risk
$\geq 50 \times 10^9$/L	Higher risk	ALL biology may change risk
CNS		
CNS3	Higher risk of CNS and bone marrow relapse	Therapy intensification, +/– cXRT
CNS2 Traumatic lumbar puncture with blasts	Higher risk of CNS relapse	CNS directed therapy intensification
Testicular	Higher risk	Therapy intensification, radiation for persistent testicular leukemia
Immunophenotype		
T cell	Higher risk	Poor outcome abolished with current therapy; nelarabine an active agent
pre-B (cIgM+)	Standard risk	Poor outcome abolished with current therapy
Early pre-B	Standard risk	Genetics may change risk
Early T-cell precursor	Adverse prognosis	Poor outcome abolished with current therapy
Ploidy		
>50 (DI >1.16) (or trisomies of chromosomes 4 and 10)	Low risk	Good response to antimetabolites, may have delayed MRD clearance, but do well provided MRD <0.1% at end induction
<44	Higher risk	Therapy intensification, high prevalence of germline *TP53* mutations
Genetic Alterations		
t(9;22)/*BCR-ABL1*	Higher risk	ABL TKI
t(4;11)/*KMT2A-AF4*	Higher risk	Potential role for proteasome inhibitors, histone deacetylase inhibitors, hypomethylating agents, BCL2 targeted agents, immunotherapy
t(1;19)/*E2A-PBX1*	Higher risk of CNS relapse	Improved outcome with current therapy
t(12;21)/*ETV6-RUNX1*	Low risk	
IKZF1	Poor prognosis Present in 80% Ph+ and also in Ph-like ALL	Potential role for tyrosine kinase, JAK inhibitors
ABL-class fusions	High risk	Potential benefits from ABL-targeting TKI
CRLF2 rearrangements	In half of Ph-like cases, associated with Hispanic/Latino, poor outcome	Potential role for JAK inhibitors
Other JAK activating lesions *(JAK1/2* fusions and activating mutations, *EPOR* rearrangements, *IL7R* lesions, *SH2B3* lesions*)*	Poor prognosis	Potential role for JAK inhibitors
DUX4 rearranged	Favorable prognosis Commonly accompanied by ERG dysregulation Frequent IKZF1 deletions but these not associated with poor prognosis	
MEF2D fusions	Possible poor prognosis, older age	Potential role for HDAC inhibition
ZNF384 fusions	Younger age, immunophenotype with weak CD10 and expression of myeloid markers; stem cell like gene expression signature; *TCF3-ZNF384* fusions associated with poor prognosis	
NT5C3 mutations	Associated with 6MP/6TG resistance and relapse	Possible role for NT5C3 inhibitors, inosine-5'-monophosphate dehydrogenase inhibition
CREBBP	Associated with drug resistance and relapse	Potential benefit from histone deacetylase inhibitors

Continued

TABLE 67.2 Prognostic Factors in Acute Lymphoblastic Leukemia—cont'd

Factor	Prognosis	Clinical Application
MRD		
Day 15 <0.01%	Excellent outcome	No benefit from 2nd delayed intensification
Day 8 PB <1%	Associated with excellent outcome in NCI SR patients with favorable cytogenetics, end induction MRD <0.01%	Do well with relatively low-intensity therapy
Day 8 PB ≥1%	Associated with higher risk for NCI SR patients with neutral cytogenetics even if end induction BM MRD <0.01%	Benefit from intensified post-induction therapy
Slow early responders	Higher MRD=higher risk of relapse Prognostic MRD threshold may be genotype specific (0.01% for most, but 0.1% for some favorable cytogenetic subsets)	Benefit from intensified post-induction therapy
End of consolidation (or after 4 months of therapy) >0.01%	Dismal outcome	Transplantation in first CR; CD19 targeting CART being explored

ALL, Acute lymphoblastic leukemia; *BM*, bone marrow; *CART*, chimeric antigen receptor T-cell therapy; *CNS*, central nervous system; *CR*, complete remission; *DI*, DNA index; *HDAC*, histone deacetylase; *JAK*, Janus kinase; *KMT2Ar*, KMT2A-rearranged; *KMT2A*^{WT}, *KMT2A* wild-type; *MRD*, minimal residual disease; *NCI SR*, National Cancer Institute standard risk; TKI, tyrosine kinase inhibitor; WBC, white blood cell.

achieve this status. Patients who are in morphologic remission but have a postinduction MRD level of 1% or more fare as poorly as those who do not achieve clinical remission by conventional criteria (≥5% blasts). Even earlier disease assessment can further refine risk stratification. The COG incorporates day 8 peripheral blood MRD into its risk stratification schema and about half of all patients show a disease reduction in the BM to 10^{-4} or lower after only 2 weeks of remission induction, and they appear to have an exceptionally good treatment outcome.[18] The persistence of MRD (≥0.01%) beyond 4 months from diagnosis was associated with an estimated 70% cumulative risk of relapse. Patients with 0.1% MRD or more at 4 months had an especially dismal outcome. COG data suggests that NCI HR patients with persistent MRD (≥0.01%) after consolidation therapy have a dismal outcome, warranting consideration of HSCT in first CR.[19] Most contemporary clinical trials have incorporated MRD detection into the risk-classification system. Although MRD positivity is strongly associated with known presenting risk features, it has independent prognostic strength, and is increasingly used in risk stratification of ALL in contemporary regimens. (See box on Minimal Residual Disease.)

MINIMAL RESIDUAL DISEASE

The rapidity of response to induction therapy is perhaps the most powerful independent predictor of outcome. There is strong concordance between the assessment of minimal residual disease (MRD) by flow cytometry and by polymerase chain reaction (PCR) methods. Most North American institutions routinely monitor MRD using the flow cytometry method because it is simple and rapid, and can be used in the vast majority of acute lymphoblastic leukemia (ALL) cases. Most European groups on the other hand more commonly use PCR of the immunoglobulin heavy chain. When compared these methodologies show strong concordance, and both readily achieve detection of residual disease to 10^{-4}. Persistence of MRD of 10^{-4} at end of consolidation or more at 4 months from diagnosis is associated with an especially dismal outcome. The adverse prognosis of high-risk slow early responders can be improved with intensification of induction and consolidation. Low-risk cases may be spared the increased risk of early morbidity and mortality from intensive induction provided that they receive postinduction intensification therapy. Novel approaches at measuring MRD at levels down to and even below 10^{-6} using next-generation sequencing of clonotypic B- and T-cell receptors are being evaluated.

Currently, pediatric patients with ALL are typically classified into risk categories based on age, leukocyte count at diagnosis, blast cell immunophenotype and genotype, as well as early treatment response. More recently, genome-wide analyses with SNP array and especially NGS have discovered many nonrandom genetic abnormalities, several of which have already been found to have prognostic and therapeutic implications.

THERAPY, INCLUDING STEM CELL TRANSPLANTATION

In contrast to Burkitt leukemia, which is treated with short-term intensive chemotherapy, therapy for B-ALL or T-ALL is administered over 2 to 3 years. Treatment starts with a 4- to 6-week remission-induction phase aiming at eradicating the initial leukemic cell burden and restoring normal hematopoiesis. The induction phase typically includes the administration of a glucocorticoid (prednisone or dexamethasone), vincristine, and asparaginase. A three-drug induction regimen appears sufficient for most low-risk cases, provided they receive appropriate post-remission therapy risk-stratified on the basis of tumor genetics and response to induction therapy. The benefit in long-term survival of addition of an anthracycline during induction is widely accepted in higher-risk patients but less clear in lower-risk patients. With this approach, 98% to 99% of patients can attain remission, as defined by less than 5% blasts in the marrow and a return of neutrophil and platelet counts to near normal levels. Intrathecal chemotherapy is usually initiated at the start of treatment but may be delayed in selected patients, as mentioned earlier.

Following remission induction, 6 to 8 months of intensive chemotherapy (generally referred to as consolidation) is given to eradicate drug-resistant residual leukemic cells and prevent CNS leukemia development. Consolidation therapy is tailored to the leukemia subtype and risk group and varies by pediatric ALL consortia. Most patients benefit from a delayed intensification (or delayed re-induction) based on the Berlin-Frankfurt-Munster protocol I, consisting of drugs similar to those used in remission induction therapy after a 3- to 4-month period of a less intensive, interim maintenance chemotherapy. Some pediatric ALL consortia utilize a double-delayed intensification with a second re-induction at week 32 of treatment as on some chemotherapy backbones this has been found to improve outcome in patients with intermediate-risk leukemia but does not benefit patients with rapid early response. (See box on Consolidation Therapy.)

CONSOLIDATION THERAPY

The importance of a consolidation phase following remission induction is undisputed, but the treatment regimen and duration varies in the different childhood acute lymphoblastic leukemia (ALL) studies. Commonly used strategies include high-dose methotrexate plus mercaptopurine, frequent pulses of vincristine and corticosteroid plus high-dose asparaginase for 20–30 weeks, and re-induction treatment with the same agents given during initial remission induction. Re-induction treatment has become an integral component of contemporary protocols. In one randomized study, double re-induction further improved treatment outcome in patients with intermediate-risk ALL, while additional pulses of vincristine and prednisone after a single re-induction course was not beneficial, suggesting that the increased dose intensity of other drugs, such as asparaginase, was responsible for the observed improvement. An "augmented" regimen including additional doses of vincristine and asparaginase during periods of myelosuppression improved outcomes of patients with a slow early response to therapy.

After completion of induction and consolidation, patients receive a 2- to 2.5-year maintenance (or continuation) phase consisting of low-intensity metronomic chemotherapy designed to eradicate any residual leukemic cell burden. Weekly low-dose methotrexate (mostly given orally) and daily oral mercaptopurine form the backbone of most maintenance regimens. Many groups add regular pulses of vincristine and corticosteroids to this regimen, although the benefit of these pulses and their optimal duration and frequency of administration in the context of contemporary therapy have not been established. Adjusting chemotherapy doses to maintain white cell count between 2 and 3 × 10^9/L and neutrophil counts between 0.5 and 1.5 × 10^9/L has been associated with a better clinical outcome. Overzealous use of mercaptopurine, to the extent that neutropenia necessitates chemotherapy interruption, reduces overall dose intensity and is counterproductive. The optimal duration of therapy remains unknown. Attempts to shorten therapy duration from 24 months to 12 or 18 months have resulted in a significant increase in relapses. Several studies showed no advantage to prolonging treatment beyond 3 years. Some consortia have historically given boys a longer duration of maintenance therapy, though the benefit of this extended maintenance phase has not been definitively established in the context of modern-era therapy.[20] Thus, most consortia have eliminated this sex-based difference in length of therapy. A small number of patients with particularly poor prognostic features may undergo allogeneic hematopoietic cell transplantation during first remission.

Radiation therapy was the first modality successfully used to prevent CNS relapse. The effectiveness of cranial radiation as preventive therapy was offset by substantial late effects in long-term survivors, including learning disabilities, multiple endocrinopathies, and an increased risk of second malignancies. Subsequent trials demonstrated that, in the context of optimal systemic and intrathecal therapy, cranial irradiation can be omitted in the vast majority of patients but reserved for a few patients with significant CNS disease at diagnosis and those who developed subsequent CNS relapse.[21] Some consortia have eliminated CNS radiation for all upfront ALL patients regardless of presenting CNS status on the basis of a collaborative group study showing that prophylactic cranial irradiation failed to improve outcome of any high-risk subgroups and in fact was associated with poor survival in several subgroups. Patients with high-risk genetic features, T-lineage ALL, and leukemic cells in the cerebrospinal fluid (CSF) even from iatrogenic introduction from a traumatic lumbar puncture at diagnosis, require more intensive CNS-directed therapy to reduce CNS relapse.[21] Studies have successfully used early intensified intrathecal methotrexate alone or triple intrathecal therapy with methotrexate, hydrocortisone, and cytarabine. Systematically administered agents including high-dose methotrexate, dexamethasone, and asparaginase also contribute to prevention of extramedullary relapses including CNS.

Based on reports of more potent in vitro antileukemic activity and better CNS penetration, dexamethasone has replaced prednisone in many induction and continuation regimens. Prednisone remains the preferred glucocorticoid for older B-ALL patients during induction because of the relative increased toxicity associated with dexamethasone use in individuals above 10 years. Polyethylene glycol–conjugated (PEG) *Escherichia coli* asparaginase is now the widely accepted first-line asparaginase preparation. Asparaginase derived from *Erwinia chrysanthemi* has a short half-life and its use is currently limited to patients who develop antibody mediated hypersensitivity to or silent inactivation of *E. coli* formulations given limited to no cross-reactivity.[22] The dose schedule for asparaginase should take into account the variability in the pharmacokinetic profile and potency among the different preparations. Intensifying asparaginase therapy during the early phase of treatment benefits high-risk patients, particularly those with T-cell disease. Significant improvement was also reported in the outcome of patients receiving early intensification consisting of intermediate- or high-dose antimetabolite therapy.[23] The optimal dose of methotrexate depends on the leukemic cell genotype and phenotype, as well as host pharmacogenetic and pharmacokinetic parameters. Escalating low-dose methotrexate or intermediate-dose methotrexate of up to 2.5 g/m^2 is adequate for most patients with standard-risk B-ALL, but a higher dose (5 g/m^2) may benefit those with high-risk B-ALL. While previously high-dose methotrexate was favored for the treatment of T-ALL patients, a study conducted by the COG suggest excellent outcomes with escalating low-dose IV methotrexate plus asparaginase.[24] Leucovorin, a folinic acid that rescues normal cells from the toxicity of methotrexate, is necessary after treatment with high-dose methotrexate. While the intensive asparaginase and high-dose methotrexate treatment has significantly improved the outcome for patients with T-cell ALL, the emergence of specific therapy like the purine nucleoside analog nelarabine will likely increase the tendency to assign patients with T-cell ALL to a specific treatment protocol or stratum.

About 10% of the population inherit one wild-type gene encoding thiopurine methyltransferase (TPMT) and one nonfunctional variant allele, resulting in intermediate enzyme activity, while 1 in 300 people inherit two nonfunctional variant alleles and are completely deficient of this enzyme that catalyzes the *S*-methylation of mercaptopurine to its inactive metabolite. Patients with heterozygous and especially homozygous deficiency of TPMT are at high risk of severe myelosuppression. Patients with poor tolerance to antimetabolite treatment should be tested for TPMT genotype or activity for selective dose reduction of mercaptopurine. Recently, *NUDT15* polymorphism was found to account for the poor tolerance of Asian and to a lesser degree Hispanic populations to mercaptopurine. Substituting thioguanine for mercaptopurine during continuation therapy was associated with a high incidence of profound thrombocytopenia and hepatic sinusoidal obstructive syndrome (formerly veno-occlusive disease). Thioguanine use has therefore been limited to short pulses administered during consolidation therapy in some trials.

As optimizing the administration of existing therapies is reaching its limit, further improvements in outcome will require the development of therapeutic approaches directed against rational therapeutic targets. The expanded understanding of the biologic, immunologic, and genetic heterogeneity of ALL has enabled development of several novel therapeutic strategies. Various monoclonal antibodies, bispecific T-cell engager antibody (blinatumomab), and autologous CD19 chimeric antigen receptor (CAR) T cells have shown promise in clinical trials leading to commercialization for treatment of B-ALL that is refractory or in second or greater relapse. More recent frontline B-ALL trials are evaluating the incorporation of blinatumomab, CD19 CAR T cells, and inotuzumab into upfront ALL regimens in standard and high-risk patients with persistent residual disease, respectively.

Dose Schedule

The biologically equivalent doses among the different formulations of corticosteroids, thiopurines, and asparaginase are not clear. Trials comparing such agents should be cautiously interpreted taking into account the dose schedule and route of administration, and the effect of variability in the pharmacokinetic profile and potency among the agents involved. Simple modification of dose, schedule, or route of administration may result in significant differences in efficacy and toxicity. Also, when comparing regimens containing high-dose intravenous methotrexate, the dose schedule of leucovorin rescue should not be ignored as it plays a crucial role in modulating the activity and toxicity of methotrexate.

Autologous transplantation has failed to improve the outcome in ALL, and thus is not incorporated into the treatment of pediatric ALL. Comparisons between allogeneic hematopoietic cell transplantation and intensive chemotherapy for high-risk patients have yielded inconsistent results due to the small number of patients studied and differences in case selection criteria. It is generally accepted that allogeneic transplantation is a treatment modality for patients with ALL who are predicted to respond poorly to intensive chemotherapy including those with persistence of MRD after post-induction phases of therapy. While continuing to evolve, at present, many would consider HSCT in first CR for patients with refractory leukemia (failure to enter morphologic remission after 4 to 6 weeks of induction therapy), high level of MRD (>1%) after remission induction, persistent MRD after consolidation treatment, and early hematologic relapse. It is crucial to reduce residual disease to, or close to, undetectable levels as the outcome is superior if MRD is undetectable prior to transplantation, and worsens with increasing MRD levels at time of transplant. Whether CAR-T-cell therapy can replace transplantation in selected patients is being tested in prospective clinical trials, which remain in their early stages (NCT03876769).

Therapeutic Innovations Being Incorporated Into Contemporary Personalized Acute Lymphoblastic Leukemia Therapy

1. Targeting genetic alterations that drive high-risk Ph-like ALL with ABL TKIs and JAK inhibitors
2. Immunotherapeutic approaches with bispecific T-cell engager antibodies, antibody-drug conjugates, and CAR-T cells
3. Proteasome inhibitors
4. Epigenetically targeted agents
5. Inhibitors of *BCL2* family members

Treatment approaches for adolescents and young adults with ALL have evolved considerably with the widespread adoption of pediatric-based protocols that appears to have significantly improved survival and decreased the need for transplantation in this age group. The benefit of allogeneic transplantation in infants with t(4;11) ALL remains controversial, and should be evaluated in the context of emerging therapies such as epigenetically targeted agents, immunotherapy, and other novel agents. As detailed above, patients with Ph-like ALL may benefit from molecularly targeted therapy that will improve their outcome without relying on transplantation. Matched unrelated-donor, haploidentical, or cord blood transplantation has yielded outcomes comparable to those obtained with matched related-donor transplantation, and should be considered reasonable alternatives if a matched donor is not available. Many advances have been made in stem cell transplantation, such as prevention of graft-versus-host disease, expansion of the pool of suitable unrelated or related donors, donor selection and tissue typing, acceleration of engraftment, enhancement of the graft-versus-leukemia effect, and supportive care. Because improvements in transplantation tend to parallel those in chemotherapy, the indications for transplantation in newly diagnosed and relapsed patients should be re-evaluated periodically. For example, the presence of the Philadelphia chromosome is no longer a clear indication for transplantation with the incorporation of ABL TKIs in treatment regimens

ACUTE LYMPHOBLASTIC LEUKEMIA RELAPSE

Most relapses occur during treatment or within the first 2 years after its completion, although relapses have been reported as late as 10 years after initial ALL diagnosis. The most common site of relapse is the BM. Relapse in extramedullary sites, such as the CNS and testes, has decreased to less than 3% and 1%, respectively. Leukemia relapse occasionally occurs at other sites, including the eye, ovary, uterus, bone, muscle, tonsil, kidney, mediastinum, pleura, and paranasal sinus. Extramedullary relapse in children with ALL frequently presents as an isolated clinical finding. However, in studies that included the MRD assay, many extramedullary recurrences were associated with MRD in the BM. A small fraction of patients experience a recurrence of acute leukemia with an immunophenotype different from that determined at diagnosis. Some of the cases represent relapse of original leukemic clones with a shift in immunophenotype, but others are secondary malignancies caused by the mutagenic effects of leukemia treatment, especially from epipodophyllotoxin. Patients with isolated BM relapse generally fare worse than those with isolated extramedullary relapse or combined BM and extramedullary relapse. Factors indicating an especially poor prognosis are short initial remission and T-cell immunophenotype. The presence of MRD at the end of second remission induction is also a strong adverse prognostic indicator. While chemotherapy may secure a prolonged second remission in children with ALL who experience late relapse (defined as more than 6 months after cessation of therapy by some consortia and BM relapse ≥36 months from diagnosis or isolated extramedullary relapse ≥18 months from diagnosis), allogeneic transplantation is the treatment of choice for patients with early relapse of B-ALL, or late B-ALL relapse with residual MRD at end re-induction I and all T-ALL relapse. A subset of B-ALL patients treated with CD19 CAR T cells as definitive therapy following relapse have experienced sustained remissions without undergoing allogeneic HSCT.[25] Patients with late-onset isolated CNS relapse who had not received cranial irradiation as initial CNS-directed therapy have a very high remission retrieval rate, with long-term prognosis approaching that of newly diagnosed patients.

Genome-wide studies using paired diagnosis and relapse samples from the same patients are exploring the genetic basis of relapse. Although 90% of the cases exhibit differential gaining or losing genetic lesions from diagnosis to relapse, most relapse samples are clonally related to diagnosis samples. Relapse clones could be present as minor populations at diagnosis and selected during treatment to emerge in the predominant clone at relapse, displaying alterations of genes that have been implicated in treatment resistance. Gain of function mutations of the gene *NT5C3*, a 5’nucleotidase, are also common in relapsed ALL. These relapse-specific *NT5C3* mutations inactivate the active metabolite of 6-mercaptopurine, rendering the mutated leukemic blasts resistant to this important component of therapy, particularly during maintenance. These paired diagnosis/relapse studies have also revealed a key role for epigenetic dysregulation in chemotherapy resistance and relapse in ALL. Almost 20% of relapsed cases have sequence or deletion mutations of *CREBBP*, which impair histone acetylation and transcriptional regulation of CREBBP targets. Other epigenetic regulators with mutations enriched at relapse include *EP300*, *KMT2D*, *NSD2*, and *SETD2*.[11] The striking enrichment of epigenetic regulator mutations at relapse suggest they are key drivers of therapy resistance, and thus epigenetically targeted therapy may be a viable means to overcome chemoresistance in ALL. The next generation of deep sequencing technologies promises to unravel many more, if not the full repertoire of genetic alterations in leukemia.

IMMUNOTHERAPEUTIC OPTIONS FOR ACUTE LYMPHOBLASTIC LEUKEMIA

The homogenous and stable expression of CD19 on greater than 95% of B-ALL, coupled with the accessibility of leukemic blasts within marrow and peripheral blood, have contributed to the considerable success of targeted immunotherapies for relapsed or refractory B-ALL. The two immunotherapeutic modalities that have had the most success to date are the bispecific T-cell engager (BiTE) blinatumomab and CAR-T-cells, both targeting CD19.

Blinatumomab (Amgen Inc., Thousand Oaks, CA, USA) is a BiTE antibody construct with dual specificity for CD19 and CD3 which allows it to simultaneously bind patients' endogenous $CD3^+$ cytotoxic T cells and $CD19^+$ leukemic blasts, resulting in T-cell-mediated cytotoxicity of malignant B cells. The short half-life of blinatumomab requires administration as a continuous infusion, typically administered in 28-day cycles. The success of blinatumomab as a single agent in relapsed, refractory adult B-ALL patients led to early phase studies in children with refractory B-ALL and more recently incorporation of cycles into upfront standard-risk clinical trials for B-ALL (NCT NCT03914625).[26,27]

Chimeric Antigen Receptor-Modified T Cells Targeting Acute Lymphoblastic Leukemia

CAR-T cells are artificial molecules manufactured in the laboratory to combine the antigen recognition capabilities of a monoclonal antibody (derived from a single chain variable fragment [scFv]) with the signaling and killing capacity of the T cell. In addition to the antigen recognition region and T-cell zeta chain, CAR-T cells contain an endodomain (responsible for providing the T-cell activation signal) and an additional costimulatory domain responsible for enhanced *in vivo* persistence.[28] Second-generation CAR-T cells containing 4-1BB or CD28 costimulatory domains can be manufactured from the peripheral blood of patients with r/r B-ALL following a leukapheresis procedure (less commonly venipuncture). CAR molecules are introduced into patients' T cells typically using a retroviral or lentiviral vector, then expanded in the presence of cytokines in the laboratory, typically over a period of 2 to 3 weeks. While artificial CAR receptors have been studied in a variety of malignancies, the CD19 CAR has been the most successful to date, and effectively altered the manner in which practitioners approach relapsed or refractory pre-B-ALL. Lymphodepleting chemotherapy (designed to deplete inherent lymphocytes and create a homeostatic cytokine milieu) followed by a single infusion of autologous CD19 CAR-T cells has produced remarkable initial responses (upwards of 70% MRD negative CRs across studies of various CD19 CAR products) in heavily pretreated B-ALL patients with limited treatment options.[29] This groundbreaking therapy led to FDA approval of the first cellular gene therapy in 2017, a CD19 CAR-T cell by the company Novartis (Kymriah [tisagenlecleucel]), approved for the treatment of pediatric B-ALL that is refractory or in second or greater relapse.[25,28] While a subset of patients experience sustained remissions, with ~60% of patients with an initial CR at 4 weeks remaining in MRD negative remission at one-year post CAR-T-cell infusion, the majority of patients receive CAR-T cells as a bridge to allogeneic HSCT. Major focuses of current research efforts include enhancing the persistence of autologous CD19 CAR-T cells (which is directly related to ongoing clinical response), reducing antigen-escape relapse variants (by targeting multiple tumor antigens including CD22 and CD20), identifying factors predictive of response, and exploring HSCT donor-derived and "off-the-shelf" immediately available sources.

It is worth mentioning that both blinatumomab and CD19-directed CAR-T cells are unable to distinguish malignant from normal B cells, thus successful treatment typically results in eradication of normal CD19-expressing B cells, necessitating long-term replacement with intravenous immune globulin in patients treated with CD19 CAR-T cells. Expanded use of these immunotherapeutic options has also required development of algorithms to manage commonly encountered adverse events such as cytokine release syndrome and neurotoxicity (see Chapter 96).

While immunotherapeutic targeting of ALL has primarily centered around the CD19 antigen, monoclonal antibodies and antibody drug conjugates targeting CD22 (inotuzumab ozogamicin [InO], BESPONSA) approved for use in relapsed or refractory adult B-ALL[30] have shown promising results and a favorable safety profile as a single agent in Phase 1 and 2 trials in pediatric patients. Thus, the current COG high-risk B-ALL study incorporates InO into frontline chemotherapy in patients who achieve End of Consolidation MRD negative status and are thus not anticipated to require allogeneic SCT, which is especially relevant given the risk of sinusoidal obstructive syndrome of the liver particularly in patients who undergo SCT and have previously received InO (NCT NCT03959085).

Promising targeted immunotherapy agents for T-ALL are also gaining traction, with daratumumab, a CD38 monoclonal antibody approved for treatment of multiple myeloma showing promising results in relapsed or refractory T-ALL (which commonly expresses CD38) in combination with standard reinduction chemotherapy (NCT03384654).

Ongoing immunotherapy research efforts are focused on increasing persistence of ALL-targeting CAR-T cells, reducing the risk of antigen loss relapse (by targeting multiple leukemia antigens on one CAR-T cell), identification of additional targets sensitive to CAR-T-cell or antibody-mediated cytotoxicity, and identifying off-the-shelf platforms for CAR-T cells including alternative immune effectors such as natural killer cells.

SUPPORTIVE CARE

Stringent supportive care significantly contributes to a favorable ALL outcome, and should be initiated at diagnosis as remission induction is associated with an increased risk from cardiovascular, metabolic, and infectious complications. All febrile patients with or without documented infection should be given broad-spectrum intravenous antibiotics until an infectious disease can be excluded. Rapid turnover of leukemia cells before and immediately after the initiation of chemotherapy leads to metabolic disturbances including hyperkalemia, hyperuricemia, hyperphosphatemia, and secondary hypocalcemia. Patients with high levels of uric acid are at risk for the development of acute kidney injury secondary to uric acid deposition in the kidneys. All patients require intravenous hydration to prevent or treat hyperuricemia and hyperphosphatemia. Allopurinol, a xanthine oxidase inhibitor, can prevent uric acid formation. Rasburicase, a recombinant urate oxidase that breaks down uric acid to allantoin (a readily excretable metabolite with 5- to 10-fold higher solubility than uric acid), is more effective than allopurinol but is associated with methemoglobinemia or hemolytic anemia in patients with glucose-6-phosphate dehydrogenase deficiency because hydrogen peroxide is a byproduct of the uric acid breakdown. Phosphate binders should also be used to prevent or treat hyperphosphatemia. Transfusions should be administered slowly in patients with severe anemia to prevent congestive heart failure. In patients with extreme hyperleukocytosis, prompt diagnosis can be established on peripheral blood, and chemotherapy should be urgently initiated (usually steroids with gradual introduction of other agents to achieve adequate response while avoiding massive tumor lysis). Packed red blood cell transfusion should be delayed until after the leukocyte count is decreased to prevent complications of leukostasis, but platelet transfusion should be administered to prevent bleeding. All blood products should be irradiated in patients who are receiving immunosuppressive therapy to prevent graft-versus-host disease. Adolescents, obese individuals, and patients with Down syndrome are at increased risk of hyperglycemia and other complications. Patients with Down syndrome are at very high risk for infectious mortality during induction and other intense phases of therapy, thus monitoring in the hospital through count recovery is recommended by many. Prophylactic use of trimethoprim-sulfamethoxazole (or pentamidine or atovaquone in patients with poor tolerance to trimethoprim-sulfamethoxazole) successfully prevents *Pneumocystis jirovecii* pneumonia. Dental evaluation at diagnosis and meticulous oral hygiene during chemotherapy minimizes the oral complications of leukemia and its treatment. It is important to distinguish between herpes simplex viral infection and chemotherapy-induced oral mucositis. Occasionally, patients have nausea and substantial pain on swallowing because of esophageal herpes simplex viral infection, candidiasis, or both. Oral candidiasis occurs frequently, especially in young children. Azole compounds (e.g., fluconazole, itraconazole, ketoconazole) are frequently used to treat fungal infections. It should be recognized that they can inhibit cytochrome P450 enzymes and increase the toxicities of various antileukemic agents, especially vincristine. On the other hand, concomitant administration of anticonvulsants that induce cytochrome P450 enzymes (e.g., phenytoin, phenobarbital, carbamazepine) increases the systemic clearance of several antileukemic agents and may adversely affect treatment outcome. Anticonvulsants that are less likely to induce the activity of cytochrome P450 enzymes (e.g., levetiracetam [Keppra]) are recommended in patients receiving chemotherapy. Photosensitive skin rash can occur during antimetabolite therapy. The rashes are erythematous, maculopapular, similar to atopic eczema, and most prominent on the face. Topical administration of simple emollients or a weak steroid preparation, and avoidance of external exposure to sunlight, should improve the skin condition. Patients with Down syndrome tolerate methotrexate poorly, and appropriate dose adjustment is indicated in them. During each clinic visit, a thorough review of all drugs should be undertaken because of potential adverse interactions among them. In fact, chemotherapy can also interact with various food (e.g., grapefruit) and supplements (e.g., St. John's wort, folic acid).

DRUG INTERACTIONS

We have not yet reached a full understanding of the contribution of genetic polymorphisms to interindividual differences in drug effects that allows us to translate this new knowledge into clinical practice. However, by simply avoiding drug interactions, one can prevent increased toxicity or reduced efficacy of chemotherapy. Phenytoin and phenobarbital induce the activity of cytochrome P450 enzymes, significantly increasing the systemic clearance of several antileukemic agents that may adversely affect treatment outcome. We substitute these anticonvulsants with gabapentin or levetiracetam in patients receiving antileukemic therapy. On the other hand, azole compounds (e.g., fluconazole, itraconazole, ketoconazole, posaconazole) can inhibit cytochrome P450 enzymes and increase the toxicities of various antileukemic agents, especially vincristine.

LATE EFFECTS OF TREATMENT

The most problematic late effects of contemporary ALL therapy include neuropsychologic impairments, bone morbidity, and obesity.[31] While neuropsychologic deficits are well-recognized side effects of cranial irradiation, intrathecal and systemic chemotherapy (especially methotrexate) can also cause brain atrophy and spinal cord dysfunction and contribute to the development of neurocognitive toxicities. Severe CNS toxicity has been attributed to cranial irradiation at doses of 2400 cGy or higher, but lower doses have also been associated with long-term neuropsychologic impairments, especially in younger children. Obesity, most prevalent among female survivors of childhood ALL, may be related to metabolic syndrome caused by treatment with cranial radiation and corticosteroids. Osteopenia, fractures, and osteonecrosis have been observed in up to 30% of survivors of childhood ALL. Osteonecrosis, which can lead to significant pain, loss of function, and total joint replacement, has been reported in approximately 8% of children with ALL, with the highest frequency observed in adolescence and young adult females. Testicular function (in boys treated with less than 6 g/m^2 cumulative dose of cyclophosphamide) and especially ovarian function are relatively unaffected by antileukemic therapy. Offspring of patients successfully treated for childhood ALL are generally expected to be as normal as the general population. However, recent studies showed that about 5% of patients with ALL inherit major cancer predisposing genes, some of which (such as TP53) have important clinical implication to the immediate family members.[9] Second malignant neoplasms, including malignant gliomas, meningiomas, and myeloid malignancies, occur with increased frequency in patients treated with regimens that included irradiation, epipodophyllotoxins, or alkylating agents.

FUTURE DIRECTIONS

As the cure rate approaches 90%, treatment response assessed by MRD measurements of submicroscopic leukemia has emerged as a powerful and independent prognostic indicator for gauging the intensity of ALL therapy. Children at high risk of relapse may now benefit from early intensification of therapy. The next goal is to reduce the intensity of therapy in children at very low risk of relapse, hence avoiding undue toxicity. The successful elimination of preventive cranial irradiation indicates that treatment reduction is feasible if done with caution and appropriate substitution with less toxic alternatives. Global genome analysis, in addition to refining leukemia classification, is helping identify potential molecular targets for therapy. Expanding the application of pharmacogenomics, a science that aims to define the genetic determinants of drug effects, while continuing to expand immunotherapeutic strategies will allow further personalized therapy in the future.

CHAPTER 68

ACUTE LYMPHOBLASTIC LEUKEMIA IN ADULTS

Shira Dinner, Sandeep Gurbuxani, Alexandra E. Rojek, Nitin Jain, and Wendy Stock

Acute lymphoblastic leukemia (ALL) is a heterogeneous group of diseases characterized by clonal proliferation of lymphoid progenitors (lymphoblasts). Improved diagnostic tools permit accurate and prompt diagnosis and aid in evaluation of minimal residual disease (MRD). There have been significant advances in the past decade toward understanding disease pathogenesis, refinement of prognostic groups, and the development of exciting new therapies directed toward specific disease subsets. These molecular targeted and immunotherapeutic approaches are transforming the treatment strategies for adults with ALL and are beginning to result in significant improvements in survival.

EPIDEMIOLOGY

It is estimated that in the year 2019, approximately 5930 new cases of ALL were diagnosed and 1500 deaths occurred due to the disease in the United States. ALL is primarily a cancer of childhood; the peak incidence (7.7 in 100,000) occurs between the ages of 1 and 4 years, and approximately 60% of the patients are diagnosed before the age of 20 years.[1] The incidence of ALL begins to decline with increasing age after the first decade of life. A second upward trend starts to emerge in the sixth decade of life, and a much smaller peak is seen in patients older than 85 years of age (1.8 in 100,000). Men have a slightly higher incidence of ALL than do women (male-to-female ratio, 1.4:1). The overall age-adjusted rate of ALL has increased from 0.93 in 100,000 in the year 1975 to 1.38 in 100,000 in the year 2015.[2] Similar increases in the incidence of ALL have also been reported in Scandinavia, the United Kingdom, and Italy. Although most investigators agree that this increase in the incidence is beyond what might be expected from better reporting, the actual cause(s) of this increased incidence remains largely speculative.

ETIOLOGY

A small minority of ALL cases (<5%) are associated with predisposing inherited syndromes such as Down syndrome, Bloom syndrome, ataxia telangiectasia, and Nijmegen breakage syndrome. However, the underlying etiology is not known in most cases. Although alcohol use, exposure to pesticides or solvents, and cigarette smoking have all been implicated, only ionizing radiation has been significantly linked to an increased risk of developing ALL. The vast majority of attempts to identify causative agents for ALL have been at best correlative; most of it borders on pure speculation and conjecture. Only recently has it been appreciated that the interaction between genetic predisposition and environmental factors involved in leukemogenesis is complex and may vary for different subtypes of ALL. Epidemiologic studies designed to identify environmental agents involved in leukemogenesis will therefore have to take into account the biologic subsets defined by morphology, immunophenotype, karyotype, and the molecular abnormalities and consider the possibility that for each of these subtypes the causative agent may well be different. To adequately investigate these issues, future studies will require collaborative efforts studying large patient populations.

Despite the limitations described, it is relevant to review some of the recent advances in our understanding of the etiology of ALL. Greaves and colleagues have used DNA obtained from neonatal blood spots to demonstrate that ALL-associated chromosomal translocations were acquired in utero (and hence a preleukemic clone) because they could be demonstrated in neonatal blood spots.[1] Furthermore, these ALL-associated chromosomal translo cations were present at a 100-fold higher rate than the incidence of leukemia. These investigators hypothesized that overt leukemia evolves as a consequence of an abnormal lymphoid proliferation that occurs in response to exposure to an as yet unidentified infectious agent(s). Supporting this hypothesis are data that suggest that day care attendance associated with early exposure to common infectious agents is associated with a lower incidence of ALL. Similarly, industrialization associated with improved socioeconomic status and exposure to common infectious agents later in life have been postulated to result in abnormal and excessive lymphoid proliferation and leukemic transformation. Finally, an infectious etiology can also be evoked to explain leukemic clusters that occur when a previously unexposed community is exposed to infectious agents brought into the community by a large influx of residents, as happens during urbanization of rural communities. However, it should be reiterated that all of these studies are at best correlative and not supported by direct experimental evidence. Furthermore, the infectious or environmental agent(s) responsible for this abnormal lymphoid proliferation remains elusive.

More recently genome-wide association studies (GWASs) demonstrated that susceptibility to ALL is polygenic. Several GWASs identified single nucleotide polymorphisms (SNPs) in eight loci influencing ALL risk at 7p12.2 *(IKZF1)*, 9p21.3 *(CDKN2A)*, 10p12.2 *(PIP4K2A)*, 10q26.13 *(LHPP)*, 12q23.1 *(ELK3)*, 10p14 *(GATA3)*, 10q21.2 *(ARID5B)*, and 14q11.2 *(CEBPE)*. ALL is biologically heterogeneous, and subtype associations have been identified for 10q21.2 *(ARID5B)* associated with high-hyperdiploid B-acute lymphoblastic leukemia (B-ALL) (i.e., >50 chromosomes) and 10p14 *(GATA3)* associated with B-cell receptor (BCR) *ABL*-like B-ALL. Vijayakrishnan and colleagues also applied GWASs to identify risk loci for B-ALL at 8q24.21 and for *ETV6-RUNX1* fusion-positive B-ALL at 2q22. Although these SNPs have been identified as risk factors for B-ALL, they do not appear to correlate with survival outcomes based on these early data.[3]

Retrospective analyses have also reported cases of therapy-related ALL (t-ALL) in patients who received chemotherapy and/or radiation for a prior malignancy. Several institutions in the United States jointly reported a higher frequency of poor-risk cytogenetic features, including KMT2A rearrangements and myelodysplastic syndrome–like abnormalities (e.g., monosomal karyotype) in t-ALL. In addition, they observed a variety of mutations among t-ALL patients, with the majority of patients exhibiting mutations that were more common in myeloid malignancies (e.g., DNMT3A, RUNX1, ASXL1), whereas others had ALL-type mutations (e.g., CDKN2A, IKZF1). Median overall survival (OS) was significantly shorter in the t-ALL cohort compared with patients with de novo ALL. Patients who were eligible for allogeneic stem cell transplant had improved long-term survival.[4] Washington University reported similar findings in a retrospective analysis at their institution, and a meta-analysis showed t-ALL had a higher risk of relapse and death than de novo ALL but outcomes were better in those who underwent transplant.[5]

Thus predisposing genetic alterations and prior chemotherapy and/or radiation exposure are emerging as some of the few known causes of ALL.

CLINICAL MANIFESTATIONS

The clinical presentation of ALL encompasses a wide spectrum of symptoms that correlate with the degree of bone marrow (BM) involvement and the resultant cytopenias, as well as the leukemic cell burden. Typical symptoms include fatigue, anorexia, night sweats, pallor, shortness of breath, bone pain, fever, and bleeding diathesis. Involvement of extramedullary sites may present with lymphadenopathy, hepatomegaly, or splenomegaly. Less commonly, ALL can involve the central nervous system (CNS), leading to headache, vomiting, lethargy, and cranial nerve palsies. Other extramedullary sites of involvement include the testis, tonsils, adenoids, breast, and gastrointestinal (GI) tract. Precursor T-cell ALL often presents with a large mediastinal mass with associated respiratory distress or possible signs of superior vena cava syndrome. Burkitt leukemia/lymphoma is frequently associated with CNS involvement and bulky adenopathy.

CLINICAL AND LABORATORY EVALUATION

The initial work-up for patients with suspected ALL is detailed in Table 68.1. All patients should undergo a detailed history and physical examination. Family history should be ascertained. Laboratory evaluation should include a complete blood count (CBC) with differential; and comprehensive metabolic panel, including liver function tests, lactate dehydrogenase (LDH), and uric acid. A coagulation profile should also be obtained, although coagulation parameters are frequently normal at diagnosis. Human leukocyte antigen (HLA) typing should be performed for patients who are potential candidates for autologous stem cell transplantation (ASCT).

All patients should undergo BM aspiration and biopsy for confirmation of diagnosis and for cytogenetic and molecular genetic evaluation. It is particularly important to send an aspirate (or peripheral blood if lymphoblasts are present) to the molecular oncology diagnostic laboratory to evaluate for the presence of the *BCR-ABL* fusion transcript using reverse-transcriptase polymerase chain reaction (PCR) because these patients will receive frontline therapy that includes a tyrosine kinase inhibitor (TKI). Skin biopsy for fibroblast culture for germline testing can also be obtained at the time of diagnostic BM biopsy if there is concern for a familial leukemia predisposition syndrome. Increasingly, chromosomal microarrays, gene expression profiling, RNA sequencing (RNAseq), and whole-genome sequencing are being incorporated into the work-up of ALL patients.

TABLE 68.1 Initial Evaluation of a Patient With Acute Lymphoblastic Leukemia

- Complete history (including family history)
- Physical examination
- CBC with differential
- Comprehensive metabolic profile, including LFTs
- LDH, uric acid
- Coagulation profile
- BM aspiration and biopsy (morphology, immunohistochemistry, flow cytometry, molecular and cytogenetic analysis)
- HLA typing of the patient (if a potential aSCT candidate)
- Lumbar puncture
- Chest radiography or CT imaging of the chest

aSCT, Allogeneic stem cell transplantation; *BM*, bone marrow; *CBC*, complete blood count; *CT*, computed tomography; *HLA*, human leukocyte antigen; *LDH*, lactate dehydrogenase; *LFT*, liver function test.

A lumbar puncture should be performed at diagnosis to determine CNS involvement. In the event of increased risk of bleeding caused by severe thrombocytopenia or risk of cerebrospinal fluid contamination caused by high peripheral blood blasts, the lumbar puncture should be performed by an experienced operator. It is prudent to administer intrathecal chemotherapy at the time of the diagnostic lumbar puncture after obtaining the necessary samples. A white blood cell (WBC) count of greater than 5/μL with morphologically identifiable blasts is considered as evidence of cerebrospinal fluid involvement by leukemia[1].

APPROACH TO DIAGNOSIS

Although evaluation of morphology and immunophenotype are sufficient for making the diagnosis, current risk stratification relies on additional cytogenetic and molecular genetic information. Data from these tests are therefore an important adjunct to the initial diagnostic work-up.

Initial laboratory evaluation starts with a CBC and morphologic evaluation of a Giemsa-stained peripheral blood smear. An abnormality of at least one of the CBC parameters is detected in more than 90% of ALL patients at the time of diagnosis. Anemia and thrombocytopenia are common. The anemia is usually a normochromic, normocytic anemia accompanied by reticulocytopenia. The hemoglobin levels range from 30 to 174 g/L, and almost 50% of the patients have hemoglobin levels below 100 g/L. The median platelet count at presentation is approximately 55 to 60 × 10^9/L, and almost 60% to 70% of patients have platelet counts below 100 × 10^9/L. Although the total WBC count may be low, normal, or elevated, neutropenia is commonly present. In a Cancer and Leukemia Group B (CALGB) study, the median WBC count at presentation was 19.3 × 10^9/L. Almost one-third of the patients are likely to present with a WBC count greater than 30 × 10^9/L. Blasts account for a variable proportion of the circulating WBCs, and the percent blast population can range from 0% to 100%. A leukoerythroblastic picture can sometimes be seen. In an extreme form, immature myeloid precursors and myeloblasts constitute the vast majority of cells in the peripheral blood. This should be kept in mind when attempting to make a diagnosis exclusively from peripheral blood. Eosinophilia as a presentation of ALL is extremely uncommon and is seen in association with specific chromosomal abnormalities, including t(5;14)(q31;q32) or, even less frequently, with 8p11-associated ALL (see Chapter 57). Eosinophilia associated with t(5;14) is reactive and due to overexpression of interleukin-3 on chromosome 5 driven by the immunoglobulin H (IgH) promoter on chromosome 14. The eosinophilia can be extremely pronounced and mask the blast population in this subset of patients.

Several metabolic abnormalities are present at the time of diagnosis and frequently reflect tumor burden. For example, LDH levels are frequently elevated, and almost 50% of the patients have levels between 300 and 1000 U/L. Elevated serum levels of calcium, potassium, and phosphorous have been noted. More importantly, elevated serum uric acid levels are frequently present and reflect tumor burden. Hyperuricemia needs to be carefully monitored and aggressively corrected to avoid renal failure, especially at the time of starting induction therapy.

MORPHOLOGY

Romanowsky-based stains such as Wright-Giemsa and Giemsa provide the greatest cytoplasmic detail for evaluation of cytomorphology of the cells in the peripheral blood smear, BM aspirate smear, and touch imprints (Fig. 68.1). Most frequently, lymphoblasts are small to intermediate in size and have scant, agranular cytoplasm. B lymphoblasts are morphologically indistinguishable from T lymphoblasts, and this distinction relies on immunophenotyping. The nuclei are usually round, with uniformly dispersed “smudgy”

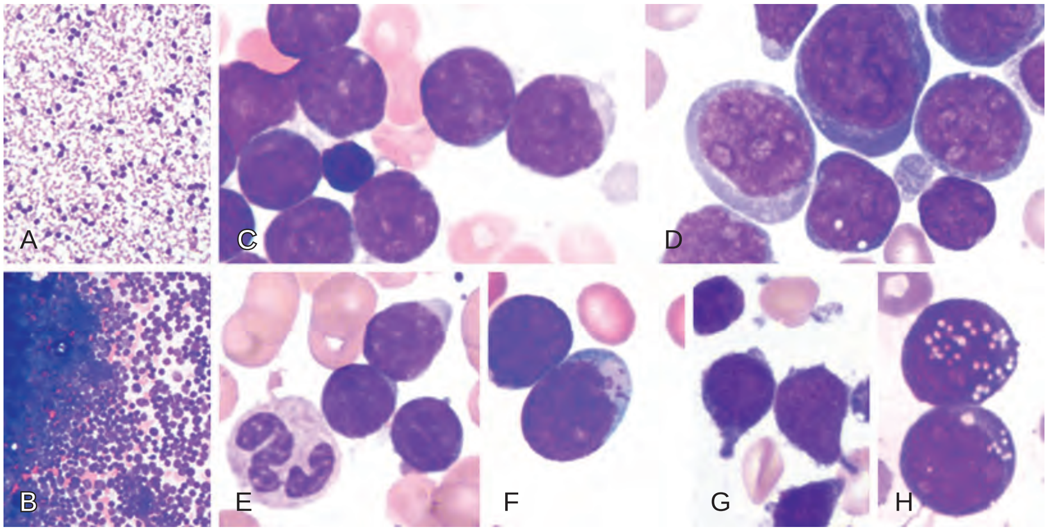

Figure 68.1 MORPHOLOGIC FEATURES OF ACUTE LYMPHOBLASTIC LEUKEMIA IN THE BLOOD AND BONE MARROW ASPIRATE. (A) In acute lymphoblastic leukemia (ALL), the peripheral blood count can be low, normal, or high, although frequently it is high and composed of mostly blasts. (B) A similar range in cellularity is true regarding the bone marrow. Typically, lymphoblasts are small to intermediate in size and have round nuclei with dispersed chromatin and indistinct nucleoli. (C) They have scant pale blue cytoplasm. A small lymphocyte (C, *middle*, *left*) is useful for comparison. (D) In many cases, the lymphoblasts are monotonous, but in some cases, the lymphoblast morphology is varied with some large cells, some cells with abundant cytoplasm, and other cells with prominent nucleoli. In the older French-American-British classification, these two patterns were referred to as ALL-L1 and ALL-L2, respectively, although they have been shown not to have any clinical significance. Other cytologic variants of lymphoblasts are shown in (E–H). These include (E) lymphocyte-like blasts, (F) blasts with azurophilic granules, (G) blasts with "hand-mirror" morphology, and (H) blasts with vacuoles. The small lymphocyte-like blasts can be difficult to distinguish from normal mature lymphocytes or chronic lymphocytic leukemia cells in the blood, making flow immunophenotyping important in the distinction. Lymphoblasts with granules can be misleading because they can be mistaken for myeloblast or monoblasts. The hand-mirror cells appear to be an artifact because they can be seen only focally on a smear. Vacuoles in the blasts can make the blasts difficult to distinguish from Burkitt cells (see also Fig. 68.7). However, flow cytometry can easily distinguish the immature ALL blasts from the mature B cells seen in a leukemic presentation of Burkitt lymphoma.

chromatin and inconspicuous nucleoli (see Fig. 68.1C). However, variations in morphology are common, and larger cells with abundant bluish gray cytoplasm, larger, somewhat irregular nuclei, and variably prominent nucleoli can be frequently seen (see Fig. 68.1D). Even though the nuclear chromatin of these cells can be fine, it is never as finely dispersed as in a myeloblast. At the other end of the morphologic spectrum are smaller cells with uniformly condensed, mature lymphocyte-like chromatin (see Fig. 68.1E), and distinction from mature B-cell malignancies relies on immunophenotyping. Coarse azurophilic granules (see Fig. 68.1F) can be seen in a subset of blasts in 5% to 8% of childhood ALLs and even more frequently in adult ALL patients. These have been reported in association with Philadelphia chromosome-positive (Ph$^+$) ALL and in ALL in Down syndrome patients. The granules are coarser than the granules seen in myeloblasts and are invariably myeloperoxidase negative (see later discussion of cytochemistry). Morphologic distinction between the L1 and L2 category recommended in the French-American-British (FAB) classification has proven to be poorly reproducible and of little prognostic value. It has been abandoned in the current World Health Organization (WHO) classification.

Cytoplasmic vacuolation (see Fig. 68.1H) can be seen in as many as 28% of childhood ALL patients. These lymphoblasts can be distinguished from leukemic presentation of Burkitt lymphoma (BL) (see later discussion) based on other morphologic features such as a smaller cell size, lack of deep blue cytoplasm, and less coarse chromatin. However, when morphology is confounding, the distinction relies on immunophenotyping of the malignant cells. In contrast to BL cells, ALL blasts are precursor B cells that express terminal deoxynucleotidyl transferase (TdT) and lack surface immunoglobulin (Ig) expression (see later discussion).

The trephine biopsy sections show hypercellular BM (Fig. 68.2). The sections are evaluated after staining with hematoxylin and eosin. The BM is usually packed with a relatively uniform population of small round blasts with round to oval nuclei. Less frequently, the blasts can be more pleomorphic, with indented, convoluted, and variably sized nuclei. The chromatin is described as being finely dispersed or stippled, and the nucleoli are usually not conspicuous. Brisk mitotic activity is almost always present. The effacement of the BM space is almost complete and uniform at the time of initial presentation. Minimal residual hematopoiesis is present; in most instances this is represented by a few megakaryocytes and some erythropoiesis. Normocellular or even hypocellular BMs at presentation have been described but are uncommon. Rarely, the initial presentation of ALL can be with an aplastic or markedly hypocellular BM. Making the diagnosis in this hypocellular context can be particularly challenging because of a paucity of material available for supporting studies such as cytogenetics and immunophenotyping.

The BM biopsy can reveal partial or complete necrosis (see Fig. 68.2C). When extensive necrosis is present, making a diagnosis can be challenging or almost impossible. A repeat BM biopsy should be attempted and will usually provide diagnostic material. Some increase in reticulin fibrosis is present in 60% to 70% of ALL patients. When fibrosis is extensive, an aspirate cannot be obtained, limiting material available for ancillary studies such as flow cytometry and cytogenetics. For these patients, the immunophenotyping can be performed by immunoperoxidase immunohistochemistry on the bone core biopsy. A second core can be obtained and submitted without fixation for cytogenetic analyses.

Organs other than the BM can be frequently involved. Extramedullary or lymphomatous presentation is more common with T-acute lymphoblastic leukemia (T-ALL) than B-ALL. The cytomorphology of the malignant cells in extramedullary disease is similar to that described in the bone core biopsy. Lymph node involvement is usually diffuse but can be partial with sparing of the follicles.

CYTOCHEMISTRY

The use of cytochemistry to assign lineage has been largely replaced by flow cytometry evaluation of the leukemic blast immunophenotype. However, when available, the myeloperoxidase reaction

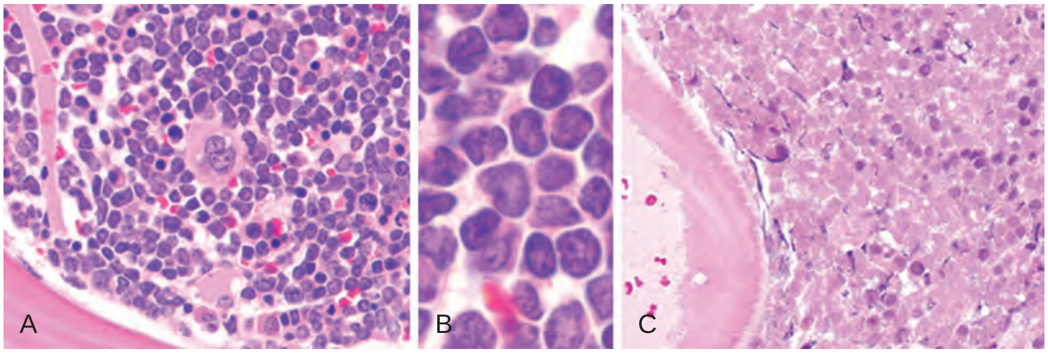

Figure 68.2 MORPHOLOGIC FEATURES OF ACUTE LYMPHOBLASTIC LEUKEMIA IN THE BONE MARROW BIOPSY. (A) The findings in the bone marrow (BM) biopsy in acute lymphoblastic leukemia are varied, but frequently the biopsy is 100% cellular and packed with blasts. Sometimes there is some residual hematopoiesis with sparing of megakaryocytes as shown. (B) A high power of the lymphoblasts is shown, illustrating the fine, dispersed, and "blastic" chromatin pattern of the cells. Sometimes the BM can be hypocellular (not shown); however, the majority of the cells in such cases are blasts. (C) Sometimes there is necrosis. The necrotic cells are referred to as "ghost" cells. They may retain some of their antigen expression as identified by immunostains; however, if the entire biopsy shows necrosis, a diagnosis should be made from the findings in the blood or a repeat BM may be necessary. Other tumors can present with BM necrosis.

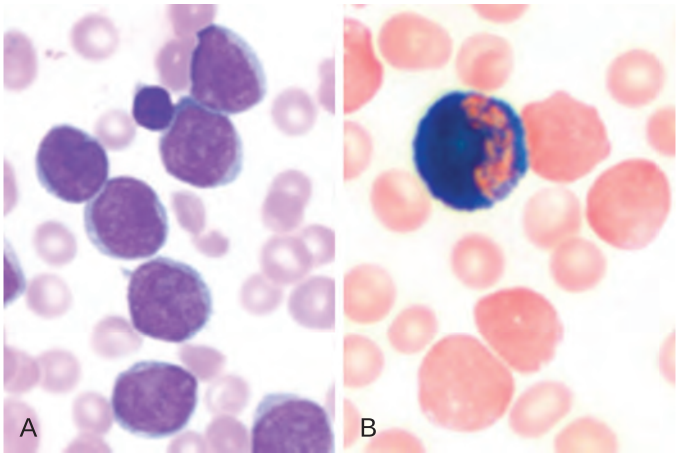

Figure 68.3 CYTOCHEMISTRY IN ACUTE LYMPHOBLASTIC LEUKEMIA. (A) The blasts in acute lymphoblastic leukemia are always myeloperoxidase reaction negative. (B) Compare the blasts with a single positively reactive granulocyte with a black-blue reaction product. Evaluating for nonspecific esterase reactivity (α-naphthyl acetate esterase, or α-naphthyl butyrate esterase) might also be performed when the blasts are difficult to distinguish from monoblasts.

(Fig. 68.3A and B) permits a rapid distinction from acute myeloid leukemia (AML). The reaction detects the myeloperoxidase enzyme in the primary granules of myeloblasts and is specific for the myeloid lineage. An acute leukemia in which 3% or more of the cells are myeloperoxidase positive is considered myeloid. There is excellent concordance between the myeloperoxidase reaction detected by cytochemistry and the myeloperoxidase molecule detected by flow cytometry.

IMMUNOPHENOTYPE

Based on large cooperative group studies in Europe and the United States, B-ALL comprises 75% to 80% and T-ALL from 15% to 25% of cases of ALL. B lymphoblasts cannot be distinguished from T lymphoblasts by morphology. Extensive immunophenotypic characterization is therefore required for the appropriate classification of ALL and indeed distinction from certain subtypes of AML. When adequate material is available, immunophenotyping should be performed using multicolor flow cytometry so that multiple antigens can be detected simultaneously on the lymphoblasts (Fig. 68.4). When interpreting the immunophenotypic data, it is important to remember that no single antigen is specific for any given lineage and multiple antigens need to be evaluated to establish the correct diagnosis. The panel of antibodies used for flow cytometry of a new leukemia and the pattern of expression seen in B-ALL and T-ALL are shown in Table 68.2. In addition, the combination of markers expressed on the B or T lymphoblasts can be reflective of the stage of development at which the transformation happened (Table 68.3). Of note, expression of myeloid antigens is seen frequently in B-ALL and T-ALL, as is the expression of T-cell antigens in B-ALL and B-cell antigens in T-ALL. Expression of individual myeloid antigens should not be a deterrent to making the diagnosis of ALL. Of particular significance is the subgroup of T-ALL that lack CD1a, CD8, and CD5 but show expression of one or more myeloid or stem cell markers and have been recently designated as *early T-cell precursor ALL*. Although these leukemias can have a gene expression profile and spectrum of genetic mutations that overlap significantly with biphenotypic leukemia, most studies suggest improved outcomes using T-ALL therapy. It is therefore best to recognize this type of ALL as a type of T-ALL rather than mixed lineage leukemia. The criteria for diagnosis of acute leukemia of ambiguous lineage, which would include mixed phenotype acute leukemia, have been extensively revised in the current WHO classification.

CYTOGENETICS AND MOLECULAR GENETICS

Chromosomal abnormalities can be detected in almost 80% of B-ALLs and 70% of T-ALLs (see Chapter 57). Cytogenetic classification remains the single most important prognostic factor in both pediatric and adult ALL. Numerical abnormalities, as well as structural abnormalities that disrupt the function of transcription factors involved in hematopoietic development and differentiation, are common. These genetic abnormalities define the biology of the disease and have an impact on treatment outcome. In addition, specific cytogenetic or molecular abnormalities are associated with unique phenotypic characteristics and are amenable to targeted therapy. *BCR-ABL1*$^+$ (referred to as Ph$^+$) ALL was the genetically defined subtype of B-ALL incorporating molecularly targeted TKI therapy in the frontline treatment. Studies over the past decade have identified the existence of a subset of B-ALL with a gene expression profile similar to that of *BCR-ABL1*$^+$ patients but without the *BCR-ABL1* fusion. This group of patients is referred to as *BCR-ABL1*–like (or Ph-like) and is also likely to benefit from targeted TKI therapy (see discussion on Philadelphia chromosome–like ALL [Ph-like ALL] later). The 2016 revision of WHO classification added the category of B-lymphoblastic leukemia/lymphoma BCR-ABL1–like to the previously recognized genetically defined entities (Table 68.4).[6]

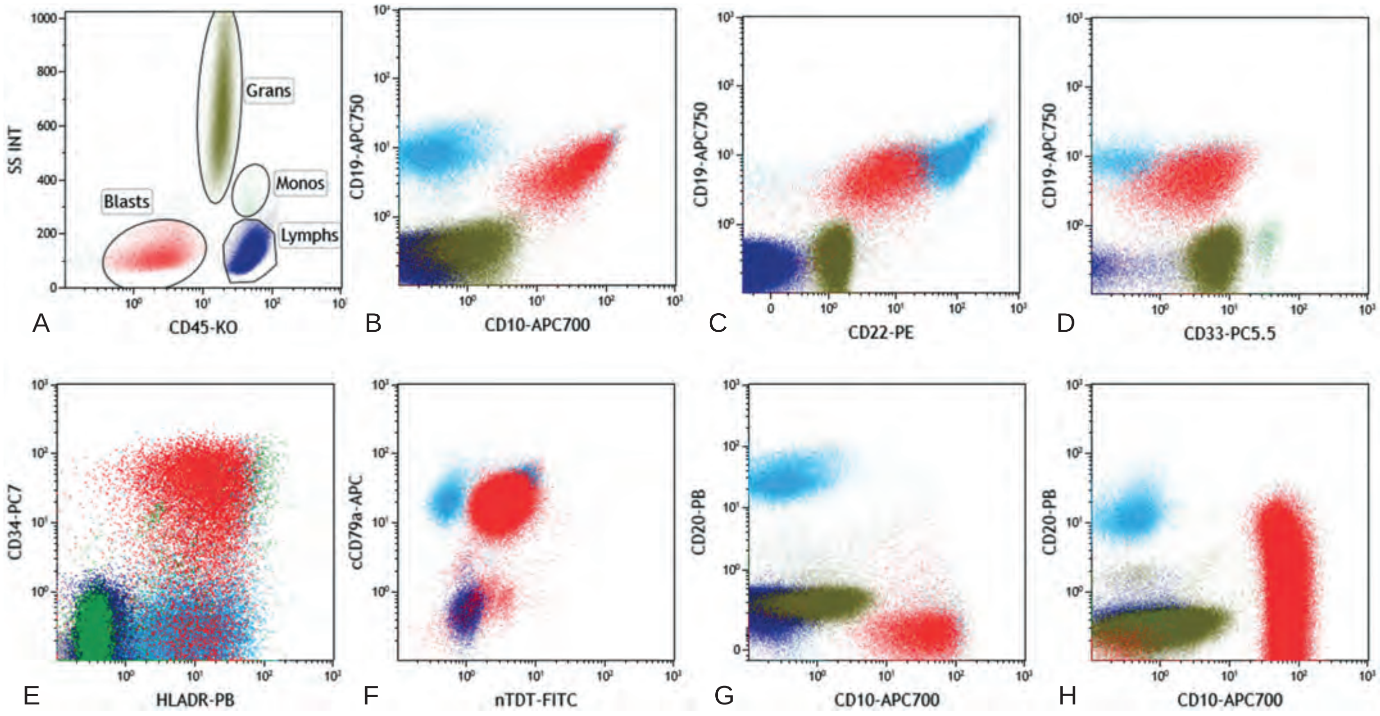

Figure 68.4 AN EXAMPLE OF FLOW CYTOMETRIC EVALUATION IN A CASE OF B-ACUTE LYMPHOBLASTIC LEUKEMIA. Selected histograms from a panel of markers used in the evaluation of acute lymphoblastic leukemia by flow cytometry are illustrated. The blasts are first identified by weak CD45 expression and low side scatter *(Blasts, red)* (A). The residual normal populations within the specimen serve as internal controls used as a reference to determine the presence or absence of an antigen as well as intensity of expression. Because no single antigen is specific for a lineage, multiple antigens are evaluated using multicolor flow cytometry. In this case, the blasts express CD19, CD10 (B), CD22 (C), myeloid antigen CD33 (intensity of expression comparable to normal granulocyte present in the specimen, D), CD34, HLADR (E), nuclear terminal deoxynucleotidyl transferase (nTDT), cytoplasmic CD79a (F), and CD10 (G). A different example shows aberrant variable expression of CD20 on leukemic blasts that express bright CD10 (H).

Hyperdiploidy, defined by the presence of more than 50 chromosomes, is seen in almost 25% of pediatric patients and 4% to 5% of adult ALL patients. In addition to routine karyotyping or fluorescence in situ hybridization (FISH) analysis, hyperdiploid DNA content can be determined by flow cytometry using DNA-binding fluorescent dyes and corresponds to a DNA content between 1.16 and 1.6. However, some studies have demonstrated that hyperdiploidy resulting from duplication of specific chromosomes (4, 10, and 17) is a better indicator of a favorable prognosis than the actual ploidy or the DNA content. Careful analysis of the specific pattern of chromosomal gains and losses or flow cytometry peaks for DNA content is required to distinguish true hyperdiploid cases from near-haploid cases that have undergone endoreplication (vide infra). In contrast to hyperdiploidy, a hypodiploid karyotype is associated with an adverse prognosis. Hypodiploid ALL with near-diploid chromosome numbers (44 to 45) is associated with somewhat distinct biology (loss of sex chromosome, dicentric chromosomes, presence of recurrent cytogenetic abnormalities such as ETV6-RUNX1) and is associated with a better outcome. In contrast, hypodiploidy with chromosome numbers less than 44 is invariably associated with poor outcome. The most common chromosome complements within the hypodiploid group are near haploid (24 to 31 chromosomes) and low hypodiploid (32 to 39 chromosomes) and are both associated with a poor outcome. Of note, low-hypodiploid ALL is frequently associated with germline *TP53* mutations and at least in a subset of cases appears to be a manifestation of Li-Fraumeni syndrome (see Chapter 66). Both near-haploid and low-hypodiploid ALL have activation of phosphatidylinositol 3-kinase (PI3K)/mammalian target of rapamycin (mTOR) and MEK-ERK signaling that can potentially be targeted by PI3K inhibitors.

A structural abnormality seen commonly in the pediatric age group but extremely rarely in the adult age group is a cryptic translocation, the t(12;21)(p13;q22) (*ETV6-RUNX1*). When present, it is associated with a favorable prognosis. Leukemias that harbor rearrangements of the mixed-lineage leukemia (*MLL*; now referred to as *KMT2A*) gene at chromosome 11q23, most notably t(4;11)(q21;q23), present with high WBC counts and frequent CNS involvement and are associated with poor clinical outcomes. Ph$^+$ ALL associated with t(9;22)(q34;q11.2) is seen in 25% of adults diagnosed with ALL. The translocation results in *BCR-ABL1* fusion, and the resulting leukemia has a poor outcome without the inclusion of TKIs into frontline treatment. Intrachromosomal amplification of chromosome 21 (iAMP21) is defined as a gain of at least three copies of regions of chromosome 21 that include *RUNX1*. The abnormality seen in 2% of B-ALL patients is associated with an older age at diagnosis and poor outcome with standard-risk therapy. iAMP21 is usually the sole cytogenetic abnormality but can be seen in patients with Ph-like ALL (see later). In addition, use of technology to assess copy number variation has identified submicroscopic genomic alterations (see Chapter 57) that have significant impact on the biology of B-ALL. These involve transcription factors such as *IKZF1* (Ikaros), *EBF*, and *PAX5*. The role of these transcription factors in B-cell development and the biology of B-ALL are discussed in greater detail in Chapter 66.

One of the most critical and clinically relevant discoveries with respect to ALL has been the description of high-risk ALL with a gene expression profile similar to that of Ph$^+$ ALL but without the *BCR-ABL1* fusion gene. This subtype of leukemia is referred to as *BCR-ABL1*–like or *Ph-like ALL*, and the kinase-activating alterations are a result of a diverse group of genetic lesions that result in dysregulated cytokine receptor and tyrosine kinase signaling. The lesions can be grouped into a surprisingly small number of broad categories. The most frequent category involves *CRLF2* rearrangements that account for almost 50% of Ph-like ALLs. The rearrangements involve either translocation of *IGH2* at locus on chromosome 14q32 to *CRLF2* on Xp22.3/Yp11.3 (pseudoautosomal region 1) or a 320-kb interstitial deletion centromeric of *CRLF2* resulting in *P2RY8-CRLF2* fusion. *CRLF2* overexpression is frequently associated with activating mutations of *JAK1*/*JAK2*, *IL7R*, or deletion of the JAK-STAT negative regulator *SH2B3*, resulting in activation of JAK-STAT signaling. JAK-STAT signaling activation also

TABLE 68.2 Antigens Used for Immunophenotyping of Acute Lymphoblastic Leukemia[a]

	Commonly Positive	Variable Expression
B-ALL	CD19[b]	CD20
	cCD22[b]	CD34
	cCD79a[b]	CD45
	Pax5[c]	CD13[d]
	CD10	CD33[d]
	sCD22	sIgM[e]
	CD24	CD58[d]
	TdT	CD38[d]
T-ALL	TdT	CD1a
	cCD3[f]	CD2
	CD7	sCD3
		CD4[g]
		CD5
		CD8[g]
		CD10
		CD34
		CD99
		CD19
		CD33[h]
		CD79a
		CD117[h]
		CD56
		CD13[h]

[a] Antigens are listed approximately in order of frequency.
[b] Almost always positive.
[c] Most specific for B lineage but can be positive in t(8;21) acute myeloid leukemia.
[d] Altered expression provides leukemia associated phenotype crucial for detection of minimal residual disease.
[e] Rarely present.
[f] Only marker considered lineage-specific.
[g] Frequently coexpressed.
[h] Along with CD5^{lo}, CD1a^{-}, CD8^{-}, the expression of these antigens is helpful in identifying early T-cell precursor acute lymphoblastic leukemia. For prognostic significance, please refer to discussion in text.
B-ALL, B-acute lymphoblastic leukemia; *c*, cytoplasmic; *IgM*, immunoglobulin M; *s*, surface; *T-ALL*, T-acute lymphoblastic leukemia.

occurs in a second category of Ph-like ALL with *JAK2/EPOR* rearrangements. The third broad category of Ph-like ALL involves *ABL1*, *ABL2*, *CSF1R*, and *PDGRB*, described together as *ABL1* class rearrangements. In addition, other kinases such as *NTRK3*, *PTK2B*, and *TYK2* have also been shown to be involved in rearrangements in sporadic cases. As preclinical studies and case reports continue to document dramatic responses to targeted therapy for this group of patients, it is imperative that these lesions be identified prospectively. Because a wide variety of lesions result in a Ph-like phenotype, the laboratory diagnosis of Ph-like ALL remains a challenge. One approach to work-up of Ph-like ALL is highlighted in Fig. 68.5.

In addition to identification of Ph-like B-ALL, recent studies that use multiple techniques including chromosomal microarrays, gene expression profiling, RNAseq, and whole-genome sequencing have identified novel genetic subtypes that had were not detectable by karyotype and FISH analyses. These genetic subtypes show alteration in PAX5, MEF2D, ZNF384, and DUX4 genes (reviewed in references 7 and 8). The incidence and impact on outcome for these abnormalities remain an area of active investigation.

Similar to B-ALL, translocations involving transcription factors are common in T-ALL. The most commonly involved genes include *HOX11* and *HOX11L2*. Other genes that are involved in T-ALL are *MYC*, *TAL1*, *LMO2*, and *LYL1*. Similar to t(12;21), translocations involving the *TAL1* gene are cryptic and require detection by molecular techniques (see Chapter 57). Activating mutations of the *NOTCH1* gene are detected in almost 50% of ALL patients (see Chapter 66). Although activating mutations of *NOTCH1* appear to be associated with disease pathogenesis, they do not appear to be associated with an adverse prognosis; in fact, some pediatric studies suggest that NOTCH1-mutated T-ALL may have a relatively favorable response to current treatment regimens. Deletions of the *CDKN2A* gene on chromosome 9p are also particularly frequent as are mutations in the *FBXW7* gene, but neither has clear prognostic significance as single abnormalities. The significance of these mutations remains an area of active research.

DIFFERENTIAL DIAGNOSIS

ALL blasts can be easily distinguished from the reactive lymphocytes which accompany viral infections, because of the precursor phenotype of these cells. Low to weak expression of CD45 and expression of one or more precursor antigens such as TdT or CD34 is useful. In addition, precursor T-ALL cells express only cytoplasmic CD3 and no surface CD3, and B-ALLs frequently lack expression of CD20 while being CD19 positive. As mentioned previously, ALL cells can have some cytoplasmic vacuoles and need to be distinguished from leukemic presentation of BL. Unlike ALL, BL cells are mature B cells with bright surface Ig expression, with very strong CD20 expression, and that lack expression of CD34. Diagnosis of BL is confirmed by the presence of an *MYC* translocation using FISH or karyotypic analyses. Other entities that require distinction from ALL depend on the age of presentation. In the pediatric age group, ALL blasts need to be distinguished from hematogones. Hematogones are normal B-cell precursors present within the BM. These are more abundant in childhood and decrease with increasing age. Hematogones may also be increased during hematopoietic regeneration, particularly after chemotherapy or BM engraftment after stem cell transplant. Hematogones possess a distinct pattern of antigen expression that recapitulates progressive B-cell maturation. This is reflected in progressive loss of antigens such as CD34, TdT, and CD10 and acquisition of CD20 and surface Ig expression (Fig. 68.6). Other diseases that need to be morphologically distinguished from ALL include small blue cell tumors, including Ewing sarcoma, neuroblastoma, and medulloblastoma. Ancillary studies, including immunophenotyping and cytogenetics, are helpful in making the distinction. In older adults, entities that can morphologically mimic ALL include blastoid mantle cell lymphoma, chronic lymphocytic leukemia, and prolymphocytic leukemia (see Chapters 76 and 86). These latter are all mature B-cell malignancies that can be distinguished from ALL based on the mature B-cell phenotype, including consistent expression of CD20 and surface Igs.

PROGNOSIS

Prognostication based on clinical and biologic risk factors has been useful in making informed decisions about postremission treatment options. Established risk factors for a poor prognosis with current chemotherapeutic approaches include age older than 60 years, elevated WBC count at diagnosis (>30,000/µL for B-cell ALL; >100,000/µL for T-cell ALL), pro–B-cell or early T-cell immunophenotype, and cytogenetics (t[4;11][q21;q23] and other *MLL* rearrangements, hypodiploidy, or a complex karyotype). The presence of the Philadelphia chromosome, t(9;22)(q34;q11.2) resulting in the *BCR-ABL* fusion gene, was previously associated with very poor treatment outcomes. Recent addition of ABL kinase inhibitors (molecularly targeted therapy), discussed in detail later, has improved the prognosis for these patients. Time to achievement of complete remission (CR) longer than 4 weeks has also been associated with a poor clinical outcome (Table 68.5).

Although different study groups have used slightly different variations of these risk factors, the presence of any one of the

TABLE 68.4 Significant Features of B-Acute Lymphoblastic Leukemia With Recurrent Cytogenetic Abnormalities in the 2008 World Health Organization Classification

Cytogenetic Abnormality	Phenotype	Clinical Correlates	Incidence
t(9;22)(q33;q11.2)	CD19$^+$, CD10$^+$, CD25$^+$; frequent expression of myeloid antigens	Seen more frequently in adults; traditionally associated with extremely poor outcome; improved early event-free survival with targeted therapy	19% of all adult ALL patients; incidence increases with age
t(v;11q23) Common fusion partners include AF4 (4q21) and ENL (19p13)	CD19$^+$, CD10$^-$; aberrant expression of myeloid antigen CD15	Frequent presentation with high WBC count, CNS involvement	9% of Ph$^-$ adult ALL
t(12;21)(p13;q22) Cryptic translocation; requires FISH	CD19$^+$, CD10$^+$; aberrant expression of myeloid antigen CD13	Sensitive disease with favorable outcome on standard therapy	2% to 3% of Ph$^-$ adult ALL
Hyperdiploidy chromosome number >50, <66 extra copies of nonrandom chromosomes, most frequently 21,X,14, and 4	CD19$^+$, CD10$^+$; no distinctive phenotype	Sensitive disease with favorable outcome on standard therapy	10% of Ph$^-$ adult ALL
Hypodiploidy chromosome number <46	CD19$^+$, CD10$^+$; no distinctive phenotype	Poor prognosis	4% of Ph$^-$ adult ALL
t(5;14)(q31;q32)	CD19$^+$, CD10$^+$; no distinctive phenotype	Reactive eosinophilia driven by IL-3 overexpression driven by the translocation; blasts may be <20% in the BM and undetectable in peripheral blood	Rare in adults
t(1;19)(q23;p13.3)	CD19$^+$, CD10$^+$; cytoplasmic μ$^+$	No significant association with response to therapy on current protocols	3% of Ph$^-$ adult ALL

ALL, Acute lymphoblastic leukemia; *BM*, bone marrow; *CNS*, central nervous system; *FISH*, fluorescence in situ hybridization; *IL-3*, interleukin-3; *Ph*, Philadelphia chromosome; *WBC*, white blood cell.
Data from Moorman AV, Harrison CJ, Buck GAN, et al. Karyotype is an independent prognostic factor in adult acute lymphoblastic leukemia (ALL): analysis of cytogenetic data from patients treated on the Medical Research Council (MRC) UKALLXII/Eastern Cooperative Oncology Group (ECOG) 2993 trial. *Blood*. 2007;109:3189; and Pui CH, Relling MV, Downing JR. Acute lymphoblastic leukemia. *N Engl J Med*. 2004;350:1535.

following is generally accepted as high risk (HR): high WBC count at diagnosis (>30,000/μL in B-cell ALL or >100,000/μL in T-cell ALL); cytogenetic abnormalities [hypodiploidy, t(4;11), t(9;22)]; age older than 60 years; pro–B-cell phenotype; and time to remission longer than 4 weeks. All other patients are considered standard risk (SR).

Nevertheless, despite being labeled as SR, up to 40% to 50% of these adults eventually relapse. Thus there is a need for refinement of prognostic markers for ALL patients. Recently, an early T-cell phenotype, the expression of CD20$^+$, and several recently described genetic mutations (*IKAROS*, *CRLF2*, and *JAK2*; reviewed earlier in this chapter) have been identified as being associated with adverse outcomes from retrospective analyses.

MINIMAL RESIDUAL DISEASE

The identification and quantification of measurable or MRD (below the level of morphologic disease detection) are now considered the key prognostic marker of disease-free survival (DFS). A variety of methods are used to detect MRD, including multiparameter flow cytometry (MFC), quantitative PCR, and next-generation sequencing (NGS); highest sensitivity is yielded from BM samples as compared with peripheral blood. While flow cytometry–based methods have issues with lack of standardization, they can detect aberrant patterns of cell surface antigen expression unique to the leukemic clone. PCR methods detect particular fusion transcripts such as *BCR-ABL* translocation, where its use has been most widespread and very well

Figure 68.5 ALGORITHM TO EVALUATE FOR PHILADELPHIA CHROMOSOME–LIKE ACUTE LYMPHOBLASTIC LEUKEMIA. Initial evaluation includes standard karyotype analysis to exclude cases with *BCR-ABL1*, *MLL*, *TCF3-PBX1*, and *ETV6-RUNX1* rearrangements. Flow cytometry for *CRLF2* can identify as many as 50% of Philadelphia chromosome–like (Ph-like) acute lymphoblastic leukemia. In the remaining cases FISH analysis can be used to identify recurrent rearrangements that contribute to a Ph-like gene expression profile. However, some cases will require additional analysis by next-generation sequencing. *B-ALL*, B-acute lymphoblastic leukemia; *FISH*, fluorescence in situ hybridization. *(Modified from Roberts KG, Li Y, Payne-Turner D, et al. Targetable kinase-activating lesions in Ph-like acute lymphoblastic leukemia. N Engl J Med. 2014;371:1005.)*

standardized as an outstanding marker for MRD detection, or clone-specific rearrangements as quantitative PCR (clone-specific IgH, or T-cell receptor [TCR] rearrangements) which are well standardized in European centers. NGS methods identify similar clone-specific gene rearrangements with a higher threshold of sensitivity at 10^{-6}. Regardless of method, many prospective studies have been performed and demonstrate the utility of MRD monitoring for prognosis and treatment stratification. The NGS methodology perhaps holds the most promise for future MRD testing given its ability to standardize methods, its higher limit of sensitivity, specificity for residual disease, and ability to track minor subclones of evolving disease. Consensus opinion has recommended MRD testing at the end of induction, in early consolidation, and approximately for every 3 months thereafter for at least 3 years, as well as immediately prior to stem cell transplantation (SCT) and serially thereafter.[8]

A recent meta-analysis of MRD in pediatric and adult ALL demonstrated that MRD negativity is associated with improved event-free survival (EFS) and OS at 10 years, when analyzing studies from 2000 to 2014.[9] Among studies of pediatric ALL, MRD negativity was associated with an EFS of 77% at 10 years and those with detectable MRD had an EFS of 32%. Among studies of ALL in adults, MRD negativity was associated with an EFS of 64% at 10 years, compared with 21% among those with detectable MRD. These findings, importantly, held true across modalities of MRD detection method, timing of MRD testing, karyotype of underlying disease, and phenotype of ALL—with none of these factors holding significance on the effect of MRD on hazard ratios of EFS or OS.

Individual studies of MRD among specific phenotypes of ALL have revealed new insights on prognosis and potential future study and/or treatment. Adult patients with Ph-like ALL, *MLL* gene rearrangements, and early T-cell precursor ALL have had relatively poor outcomes with standard aggressive chemotherapy regimens and are more likely to have persistent MRD positivity after intensive therapy,[10] guiding many physicians to intervene with allogeneic stem cell transplant during first CR for these subsets.[11] By contrast, with the addition of novel TKIs and targeted immune therapies, the absence of MRD during intensive frontline treatment of Ph$^+$ ALL may be changing the general recommendation away from allogeneic stem cell transplant in first remission for all eligible patients. Among Ph$^+$ ALL patients receiving a *BCR-ABL1* TKI who achieved a complete molecular remission (CMR), defined as absence of detectable MRD, after intensive chemotherapy and a TKI, who additionally did not undergo a stem cell transplant, a 4-year OS rate of 66% was achieved. Of note, the median OS for those achieving a CMR at 3 months was a statistically significant 127 months versus 38 months for those who did not achieve CMR by real-time-PCR detection of *BCR-ABL1* transcripts.[12] Similarly, Ph$^+$ ALL patients who received lower-intensity regimens after achieving CMR have been shown in a GIMEMA (Gruppo Italiano Malattie Ematologiche) study to have superior survival outcomes on TKI maintenance therapy post induction, despite not continuing on to higher-intensity chemotherapy and/or allogeneic stem cell transplant.[13]

In addition to its prognostic relevance, MRD is becoming more widely accepted as an acceptable clinical end point in clinical trials and drug approval. Blinatumomab, the bispecific monoclonal T-cell engager antibody binding CD3 and CD19, has been approved for treatment for MRD-positive disease. The use of MRD as an end point or prognostic marker may facilitate more rapid evaluation of new, emerging therapies, which might allow one to assign highest priority for early-phase trials which demonstrate low rates of MRD for continued development and approval in phase III studies to evaluate survival.[14]

TREATMENT OF ACUTE LYMPHOBLASTIC LEUKEMIA

Historical Perspective

Combination chemotherapy is the cornerstone of ALL management. In the 1960s, investigators at the National Institutes of Health designed multidrug chemotherapy regimens given over many different courses for pediatric ALL patients. A similar approach was then introduced for adults with ALL. The Berlin-Frankfurt-Muenster (BFM) group in the 1980s conducted pioneering studies and showed that an intensive multidrug induction and consolidation chemotherapy followed by delayed intensification led to improvement in survival in the majority of children. These regimens combine drugs with varying mechanisms of action at different doses, often in complex schedules, which have largely evolved empirically. Only a few of these drugs have been tested individually in randomized clinical trials in adults with ALL; therefore the relative contribution of each of the drugs in a multidrug regimen to the overall outcome is difficult to assess. Because there is an increased propensity for CNS involvement in ALL patients, all treatment regimens must also include CNS prophylaxis with intrathecal chemotherapy with or without cranial radiation. Adult ALL regimens have typically evolved from the BFM regimen using similar but often less-intensive treatment.[15]

The therapy for ALL is typically divided into three phases: (1) the remission induction phase, (2) remission consolidation or intensification, and (3) the maintenance (or continuation) phase. The remission induction and consolidation phases typically involve blocks of monthly treatment for 6 to 8 months followed by long-term maintenance, which is given for up to 3 years; thus the treatment of ALL is long and challenging and requires tremendous attention to detail, compliance, and support. Because of these challenges and the relative rarity and biologic heterogeneity of the disease, it is recommended that patients are referred to larger academic centers for evaluation and treatment to ensure the best possible survival rates. In the ensuing sections, the various components of treatment are reviewed. Special attention to the treatment of certain disease subsets is addressed because treatment of ALL is becoming increasingly based on its heterogeneity and the ability to adapt therapy to each of these subsets.

Effective chemotherapy regimens must be supplemented with adequate supportive care measures to obtain the best patient outcomes. Given the highly immunosuppressive nature of ALL treatment regimens, prophylaxis for *Pneumocystis carinii* with trimethoprim-sulfamethoxazole should be initiated early during treatment and

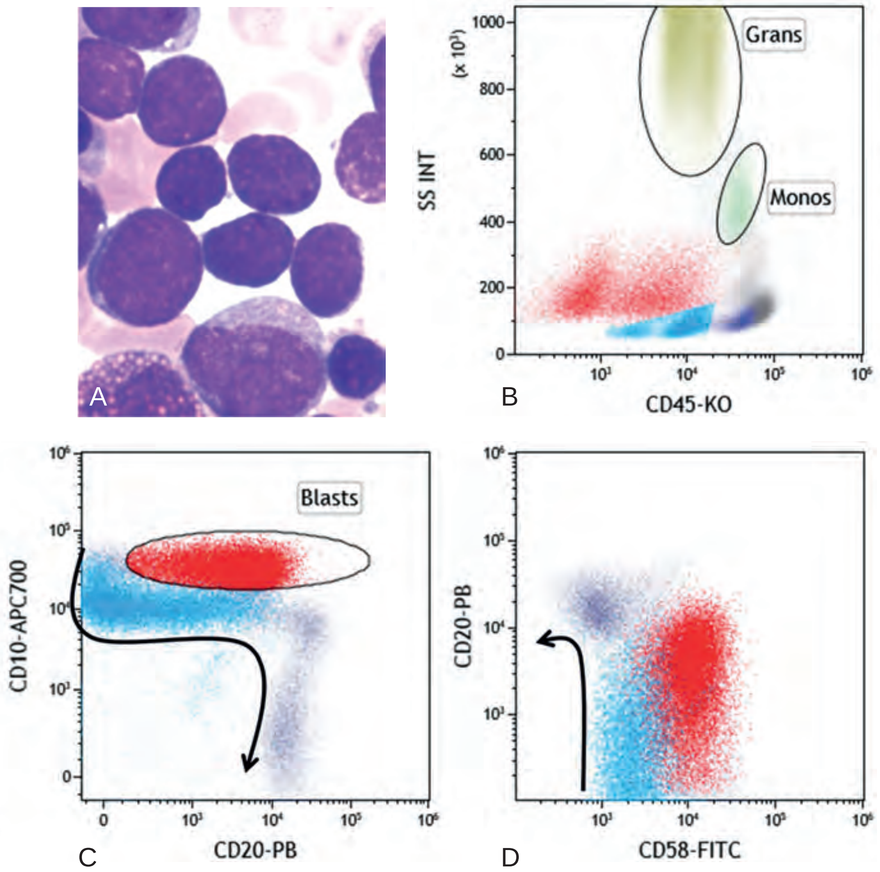

Figure 68.6 HEMATOGONES AND FLOW CYTOMETRIC EVALUATION OF MINIMAL RESIDUAL DISEASE. Hematogones are nonmalignant immature precursor B cells that are present in the bone marrow (BM). They are more commonly seen in pediatric patients but can be seen in adults during BM regeneration or associated with other conditions. (A) They can be difficult to distinguish morphologically from malignant lymphoblasts because the cytologic features overlap significantly. (B–D) Unlike malignant lymphoblasts, hematogones exhibit a spectrum of maturation that can allow distinction from leukemic blasts. The example shown here is for a bone marrow with residual B-acute lymphoblastic leukemia (B-ALL) along with hematogones. Blasts are shown in red, hematogones in aqua, and mature B cells in dark blue. Hematogones have a distinct side scatter/CD45 profile when compared with hematogones (B). Like leukemic blasts, hematogones are CD10$^+$, but as CD20 is expressed, CD10 is diminished. Lymphoblasts, on the other hand, frequently exhibit maturation arrest and expression of antigens with abnormal intensity. In the example shown (C), hematogones show progressive maturation while the blasts show maturation arrest with aberrantly bright expression of CD10. Similarly, image D shows aberrantly bright expression of CD58 when compared with hematogones. These patterns can be used to identify minimal residual disease *(right histogram)* and distinguish regenerative hematogones from residual or recurrent blasts *(red)* after therapy. Multiple markers and parameters are usually used to study posttherapy specimens in this way.

continued throughout the consolidation and maintenance phases of chemotherapy. It is also reasonable to consider antifungal and antiviral prophylaxis during periods of neutropenia. Consideration may be given to antibacterial prophylaxis during periods of neutropenia. Fluoroquinolones such as levofloxacin are the preferred agent, although the optimal antibiotic choice should depend on local bacterial resistance patterns. Neutropenic fever in this group of patients must be treated as a medical emergency with immediate institution of intravenous (IV) antibiotics after obtaining the necessary cultures.

In an attempt to decrease the duration of neutropenia and improve remission rates, several groups have studied the role of granulocyte colony-stimulating factor (G-CSF) or granulocyte-macrophage colony-stimulating factor (GM-CSF) during induction therapy. In the CALGB 9111 trial, 198 adults with untreated ALL were randomized to receive G-CSF (beginning 4 days after the start of induction until neutrophil recovery) versus placebo.[16] The median time to neutrophil recovery (≥1000/μL for 2 days) was significantly shortened to 16 days in the G-CSF arm compared with 22 days in the placebo arm. The duration of hospitalization was also significantly shorter in the G-CSF arm. There was a trend toward increased CR rates in the G-CSF arm. However, the infectious complications, DFS, and OS were similar in the two arms. Thomas and colleagues randomized 236 ALL patients treated on the France-Belgium Group for Lymphoblastic Leukemia in Adults (LALA)-94 trial to receive G-CSF, GM-CSF, or no CSF. Use of G-CSF was associated with a significant decrease in time to neutrophil recovery, duration of hospitalization, and infections that were grade 3 or higher.[17] Thus use of G-CSF can allow for faster hematopoietic recovery, especially in older adult patients, and may decrease infectious complications; however, the prophylactic use of G-CSF has not been uniformly adopted, and many studies simply follow standard guidelines for use of growth factors in the setting of neutropenic fever.

All patients should be monitored carefully for tumor lysis syndromes, especially those with risk factors such as elevated WBC counts, renal dysfunction, and elevated LDH at presentation. Patients must be provided adequate hydration and prophylaxis or treatment for hyperuricemia with allopurinol for the first week of induction. Rasburicase, a urate oxidase, can be considered for the treatment of hyperuricemia in cases with high proliferation rates.

REMISSION INDUCTION

The aim of induction therapy is to achieve maximal reduction of the leukemic burden to result in morphologic remission (<5% blasts with trilineage hematopoiesis) and normalization of the blood counts, with

TABLE 68.5 Markers for Poor Prognosis in Adult Acute Lymphoblastic Leukemia

Established Risk Factors	
Age	>60 years
Presenting WBC count	>30,000/µL (B-cell ALL); >100,000/µL (T-cell ALL)
Immunophenotype	Pro-B cell; early T cell[a]
Cytogenetics	t(4;11)(q21;q23) and other *MLL* rearrangements
	t(9;22)(q34;q11.2)—Philadelphia chromosome
	Hypodiploidy (<44 chromosomes)
	Complex (>5 abnormalities)
Therapy response	Time to complete remission >4 weeks
MRD	≥0.01% at 3–6 months after initiation of therapy[b]
Emerging Risk Factors	
Immunophenotype	CD20
Molecular	BAALC
	FUS
	ERG
	IKZF1[c]
	Ph-like ALL

[a] Initial report characterizing ETP ALL showed a poor outcome. However, subsequent studies have shown variable association with response to therapy.
[b] Different studies have used different time points for MRD assessment.
[c] Focal deletions in IKZF1 are present in up to 70% of Ph-like ALL. However, IKZF1 deletions are associated with adverse outcome irrespective of association with Ph-like phenotype.
ALL, Acute lymphoblastic leukemia; *ETP*, early T-cell precursor; *MRD*, minimal residual disease; *Ph*, Philadelphia chromosome; *WBC*, white blood cell.

as little toxicity as possible. This is typically achieved using combination chemotherapy consisting of four or five systemically administered drugs and intrathecal chemotherapy over a period of approximately 3 to 4 weeks. Most current ALL induction regimens in adults are modeled after pediatric regimens, and include a prolonged course of oral corticosteroid (prednisone or dexamethasone), weekly vincristine, and either weekly or pulsed anthracycline (doxorubicin, daunorubicin, or mitoxantrone). Many groups (CALGB,[15] French Group for Research in Adult Acute Lymphoblastic Leukemia [GRAALL] 2003,[18] Japanese Acute Leukemia Study Group [JALSG][19]) have also used twice-weekly L-asparaginase as part of induction therapy, and some have added cyclophosphamide (GRAALL 2003,[18] German Multicenter Acute Lymphoblastic Leukemic protocol [GMALL] 07/2003,[20] CALGB 8811[15]). With the current treatment regimens, very high CR rates in adults with ALL have been achieved in the range of 84% to 94% (Table 68.6). There have been few randomized comparisons between these different induction regimens; therefore the choice of the regimen should depend on the treating physician's experience with a particular regimen. Most ALL regimens are designed to optimally deliver a variety of chemotherapeutic agents; thus an entire treatment program should be selected at the time of diagnosis based on the patient's performance status and biologic risk factors. Whenever possible, these patients should be referred to centers that offer expertise in the treatment of ALL and where enrollment into clinical trials is available. Once a specific regimen has been selected, the goal (and challenge) is for both the medical team and the patient to adhere to the recommended treatments, which are arduous and lengthy in duration.

Traditionally, prednisone was the corticosteroid of choice during induction therapy for ALL trials. Studies in pediatric patients have shown lower relapse rates but higher toxicity (more sepsis, higher incidence of osteonecrosis) with dexamethasone. Dexamethasone penetrates the blood-brain barrier effectively and therefore may offer more direct CNS protection than prednisone. Randomized studies of prednisone versus dexamethasone during induction have not been performed in adults; however, both have been used during induction and postremission therapy. Anthracyclines form an important part of induction therapy. In an early trial from the CALGB,[26] patients were randomized to receive vincristine, prednisone, and L-asparaginase with or without daunorubicin. Significant improvements in CR rates and remission duration were noted with the addition of daunorubicin; anthracyclines have since become standard components of induction chemotherapy in adult and pediatric ALL. Different anthracyclines (doxorubicin, daunorubicin, and mitoxantrone) are thought to be clinically equivalent, and, to date, dose intensification of anthracycline during induction has been tested in a variety of prospective clinical trials but has not been shown to definitely improve already high CR rates or to result in significant benefits in DFS.[22,27] Addition of pulsed cyclophosphamide to induction chemotherapy has been studied with conflicting results. In the CALGB 8811 trial, addition of cyclophosphamide to the induction regimen was shown to lead to improved responses compared with historical control participants.[15] However, in a prospective, randomized Italian GIMEMA 0288 study, the addition of cyclophosphamide did not influence CR rate or survival.[23]

L-asparaginase (asparaginase) is also an important component of ALL therapy and has been incorporated into most ALL trials beginning with induction. ALL cells are unable to produce asparagine and are dependent on plasma levels of this amino acid for protein synthesis. Depletion of asparagine results in inhibition of protein synthesis and subsequent apoptotic leukemic cell death. Traditionally, native enzyme derived from *Escherichia coli* has been used. However, this preparation can be immunogenic, leading to hypersensitivity reactions and development of cross-reacting antibodies; this preparation, although still used elsewhere, is no longer available for administration in the United States. Polyethylene glycosylated (PEG)-asparaginase, formed by covalently attaching PEG to the native *E. coli* enzyme, has been developed and offers lower immunogenicity and a longer half-life. Douer and colleagues treated 25 newly diagnosed adult ALL patients (median age: 27 years; range: 17 to 55 years) with the adult ALL BFM protocol in which 14 injections of *E. coli* asparaginase were replaced by a single dose of pegaspargase (2000 IU/m^2 IV) on day 16 of induction therapy. After the single dose, asparagine deamination was complete in all patients after 2 hours and in 100%, 81%, and 44% on days 14, 21, and 28, respectively. No allergic reactions or pancreatitis was observed, and a CR was achieved in 24 of the 25 patients.[28] The CALGB 9511 trial used pegaspargase (2000 IU/m^2 subcutaneously, two doses during induction and two during first intensification) as part of the five-drug induction regimen. Of the 85 evaluable patients, those with effective asparagine depletion (defined by enzyme levels >0.03 U/mL plasma for 14 consecutive days after pegaspargase administration) had improved DFS and OS compared with those without effective asparagine deletion.[29] Thus use of pegaspargase is generally safe and effective in adults and has replaced native L-asparaginase as the agent for asparagine depletion. In 2011 the US Food and Drug Administration (FDA) approved asparaginase derived from *Erwinia chrysanthemi* to treat ALL patients who develop a hypersensitivity reaction to *E. coli*–derived asparaginase and pegaspargase; 25,000u/m^2 of Erwinia asparaginase given every 48 hours for six doses (for every one dose of pegasparaginase) has demonstrated safety and results in effective asparagine depletion in pediatric and adult ALL. Patients receiving *Erwinia* asparaginase are still at risk for known toxicities of asparaginase, including bleeding, clotting, transaminitis, and pancreatitis. In 2020, due to supply issues, a new *Erwinia* asparaginase has been approved.[30] To avoid hypersensitivity reactions, a novel preparation of L-asparaginase in which L-asparaginase is encapsulated within red blood cells (GRASPA [erythrocytes encapsulating L-asparaginase]) has been in clinical development in Europe but has not to date received approval from the regulatory agencies.

One of the regimens that is widely used in the United States and that also results in high CR rates of approximately 90% is the hyper-CVAD (cyclophosphamide, vincristine, adriamycin, and dexamethasone) regimen developed at the MD Anderson Cancer Center. The hyper-CVAD regimen differs from the pulsed weekly therapy developed by the pediatric groups and consists of four cycles of intensive

TABLE 68.6 Clinical Trials With Various Chemotherapy Regimens for Adult Acute Lymphoblastic Leukemia

Trial	Patients *(n)*	Age in Years, Median (Range)	CR Rate (%)	Disease-Free Survival	Overall Survival	Comments
CALGB 8811[15]	197	32 (16–80)	85	46% at 3 years	36 months (median)	Five-drug induction regimen based on pediatric trials with earlier and more intensive L-asparaginase
CALGB 9111[16]	198	35 (16–83)	85	40% at 3 years	23 months (median)	Patients randomized to G-CSF vs. placebo; G-CSF significantly decreased time to neutrophil recovery and CR rate with no effect on DFS, OS, or toxicities
MDACC hyper-CVAD[21]	288	40 (15–92)	92	38% at 5 years	32 months (median)	Long-term follow-up results of hyper-CVAD regimen; regimen does not include asparaginase
GMALL 07/2003[20]	713	34 (15–55)	89		54% at 5 years	Risk-adapted SCT for HR and very HR groups
LALA 94[17]	922	33 (18–79)	84	30% at 5 years	23 months (median)	CR rate similar between IDA and DNR arms; significantly higher TRM with IDA; improved DFS for the IDA arm for patients receiving only chemotherapy; for SR patients, intensive consolidation did not affect outcomes
JALSG ALL-93[19]	263	31 (15–59)	78	30% at 6 years	33% at 6 years	Doxorubicin dose intensity did not improve outcomes; during maintenance phase, early sequential intensification compared with intermittent intensification did not affect DFS
JALSG ALL-97[22]	404	38 (15–64)	74	33% at 5 years	32% at 5 years	Induction and maintenance based on CALGB 8811; dose-intensive doxorubicin during consolidation did not improve outcomes
GIMEMA 0288[23]	778	28 (12–60)	82	33% at 9 years	29% at 9 years	Addition of cyclophosphamide to induction did not influence CR rate or survival; responders to prednisone pretreatment had favorable outcomes
MRC UKALLXII/ ECOG E2993[24]	1646 (Ph$^-$)	(15–64)	90		43% at 5 years	Largest ALL trial to date; in a donor vs. no-donor analysis, those with a donor had improved OS and lower relapse rate; ASCT cannot replace consolidation or maintenance chemotherapy in any risk group
PETHEMA ALL-93[25]	222 high-risk ALL	27 (15–50)	82	35% at 5 years	34% at 5 years	Did not show beneficial effect of aSCT compared with ASCT or chemotherapy
GRAALL-2003[18]	225 Ph$^-$ ALL	31 (15–60)	94	59% at 3.5 years	60% at 3.5 years	Pediatric-inspired treatment regimen; in a historical comparison, significant increases in CR, EFS, and OS rates compared with LALA-94 trial; OS was improved for patients younger than 45 years only

ALL, Acute lymphoblastic leukemia; *aSCT*, allogeneic stem cell transplantation; *ASCT*, autologous stem cell transplantation; *CALGB*, Cancer And Leukemia Group B; *CR*, complete remission; *CVAD*, cyclophosphamide, vincristine, adriamycin, and dexamethasone; *DFS*, disease-free survival; *DNR*, daunorubicin; *EFS*, event-free survival; *G-CSF*, granulocyte colony-stimulating factor; *HR*, high risk; *IDA*, idarubicin; *OS*, overall survival; *Ph*, Philadelphia chromosome; *SCT*, stem cell transplantation; *SR*, standard risk; *TRM*, transplant-related mortality.

infusional cyclophosphamide, vincristine, doxorubicin, and dexamethasone alternating with four cycles of high-dose methotrexate and high-dose cytarabine for a total of eight intensive treatment cycles.[21]

Because CD20 is expressed on 20% to 40% of pre-B lymphoblasts and has been noted to be associated with adverse prognosis, the investigators at MD Anderson subsequently added rituximab to a modified hyper-CVAD regimen for patients with CD20 expression greater than or equal to 20%. In younger patients (≤60 years of age), rituximab improved 3-year OS to 75% compared with 47% in the historical control participants; however, no difference was seen for older adults.[31] The GRAALL 2005 study in ALL patients 18 to 59 years old included a randomization for the addition of rituximab to chemotherapy in CD20$^+$ patients. Rituximab plus chemotherapy resulted in an improved EFS of 65% compared with 52% in the chemotherapy only arm.[32] Based on these and other studies, rituximab is now generally recommended for all B-ALL patients with CD20 expression.

Some groups have also routinely instituted a 5- to 7-day steroid prophase before starting the induction therapy. This results in gentle cytoreduction and reduces the risk of tumor lysis. The achievement of rapid cytoreduction during this steroid prophase has also been shown to be of prognostic value in several studies.[33]

In summary, traditional induction regimens in adults with ALL result in very high CR rates of 80% to 90%. Until recently, OS rates have hovered at 40% to 45% (see Table 68.6) due to emergence of resistant disease. Advances that are described later are resulting in significant improvements in survival for both younger and older adults with ALL.

POSTREMISSION THERAPY

As mentioned earlier, 80% to 90% of adults with previously untreated ALL achieve CR with induction chemotherapy. However, all patients relapse if no further chemotherapy is given. This underscores the need for effective post-remission management strategies for these patients in first CR (CR1). As described earlier, adult patients with ALL have traditionally been stratified into SR or HR.

The type of recommended postremission strategy is to be based on the risk (risk-adapted approach), which implies more aggressive therapeutic approaches for HR groups compared with the SR group. There have been three tested approaches for postremission therapies: (1) postremission chemotherapy modules followed by long-term maintenance chemotherapy as per pediatric regimens; (2) allogeneic stem cell transplant; and least frequently, (3) ASCT. Studies using these postremission strategies are reviewed later.

The optimal postremission strategy for SR adult patients is not clear. Postremission chemotherapy typically follows pediatric regimen and consists of a variety of non–cross-resistant chemotherapeutic agents administered in treatment "modules" for a total of 6 to 8 months after achievement of remission. The postremission modules are typically 4 to 6 weeks in length and are modeled after successful pediatric regimens and often consist of consolidation module(s), interim maintenance modules that often focus on CNS prophylaxis (described in more detail below), and a late intensification module(s), which is often quite similar to the induction chemotherapy course. The specific drugs and the sequence or combinations in which they used are different for each protocol but typically include cyclophosphamide, L-asparaginase (or pegasparaginase), methotrexate, cytarabine, 6-mercaptopurine, vincristine, and doxorubicin. Many of these protocols have evolved empirically with few randomized trials evaluating the impact of any of the modifications that have been developed (see Table 68.6).

A different approach to postremission therapy has been taken by the MD Anderson Cancer Center, which has reported long-term results of the hyper-CVAD regimen (also listed in Table 68.6). As described earlier in the induction section, patients received alternating cycles of hyperfractionated cyclophosphamide, vincristine, adriamycin, and dexamethasone (hyper-CVAD) (courses 1, 3, 5, and 7) alternating with high-dose methotrexate and cytarabine (courses 2, 4, 6, and 8) followed by maintenance therapy for 2 years with 6-mercaptopurine, methotrexate, vincristine, and prednisone (POMP). They identified the following factors to be independent poor prognostic factors for survival: older age, Ph^+ disease, leukocytosis, thrombocytopenia, poor performance status, and hepatomegaly. The 5-year OS for the good-risk (risk score: 0 to 1), intermediate-risk (risk score: 2 to 3), and poor-risk groups (risk score: ≥ 4) were 62%, 34%, and 5%, respectively.[21]

Adults older than the age of 60 years have uniformly fared poorly with traditional chemotherapy approaches, with an OS below 10%. The most significant adverse risk factor is the presence of MRD after induction or consolidation chemotherapy. Blinatumomab, a bispecific CD19-directed CD3 T-cell engager monoclonal antibody was investigated in a phase II, single-arm study for adults with B-cell precursor ALL in hematologic CR with MRD (N^{-3}). Patients received blinatumomab 15 μg/m^2/day by continuous IV infusion for up to four cycles. Eighty-eight (78%) of 113 evaluable patients achieved a complete MRD response. Complete MRD responders had longer relapse-free survival (RFS) (23.6 vs. 5.7 months) and OS (38.9 vs. 12.5 months) compared with MRD nonresponders.[14] Based on these findings blinatumomab was granted accelerated FDA approval for the treatment of adult and pediatric patients with B-cell precursor ALL in first or second CR with MRD greater than or equal to 0.1%. These data suggest that chemotherapy alone was not effectively managing MRD and that the addition of immunotherapies such as blinatumomab to chemotherapy may improve outcomes. The Eastern Cooperative Oncology Group (ECOG) 1910 clinical trial in adults 30 to 70 years old is currently addressing the use of blinatumomab in frontline B-ALL treatment during consolidation. The study randomized all MRD-negative patients to receive blinatumomab in addition to chemotherapy versus chemotherapy alone. The primary objective of the study is to determine if the addition of blinatumomab to chemotherapy in newly diagnosed B-ALL improves OS. The study has completed accrual and is pending analysis for publication.

Table 68.6 summarizes the major treatment questions, therapeutic approach, and results of several large prospective cooperative group trials performed in the United States and Europe.

CENTRAL NERVOUS SYSTEM DISEASE: PROPHYLAXIS AND TREATMENT

Involvement of the CNS (Fig. 68.7) is uncommon at the time of diagnosis, with most series reporting it at less than 10%. However, because many patients with CNS involvement may not be referred for clinical trial enrollment, this may be an underestimate of the true rate. In the MRC United Kingdom Acute Lymphoblastic Leukemia (UKALL) XII/ECOG E2993 trial, of the 1508 eligible patients, 77 (5%) had CNS involvement at diagnosis.[24] Similarly, the French group reported a 7% (104 out of 1493 patients) incidence of CNS disease at diagnosis. Risk factors for CNS disease at diagnosis have varied in different studies. In the French trial (LALA-94), risk factors included mediastinal mass associated with precursor T-cell immunophenotype, lymphadenopathy, higher hemoglobin level, and absence of the Ph chromosome.[17] In the MRC trial, the risk factors included a higher WBC count, precursor T-cell immunophenotype, and mediastinal mass. The presence of CNS disease at diagnosis has been shown not to affect the CR rate. The French group also reported no significant difference in the OS in patients with and without CNS disease at diagnosis. However, in the MRC trial, the OS at 5 years was lower in the group with CNS disease (29% vs. 38%; $P = .03$), and they also reported that patients with CNS disease at diagnosis were twice as likely to relapse in the CNS. In the French study, younger age (<30 years), male gender, absence of the Ph chromosome, achievement of CR with one course, and use of transplant as postremission therapy had favorable impact on OS for patients presenting with CNS disease at diagnosis.

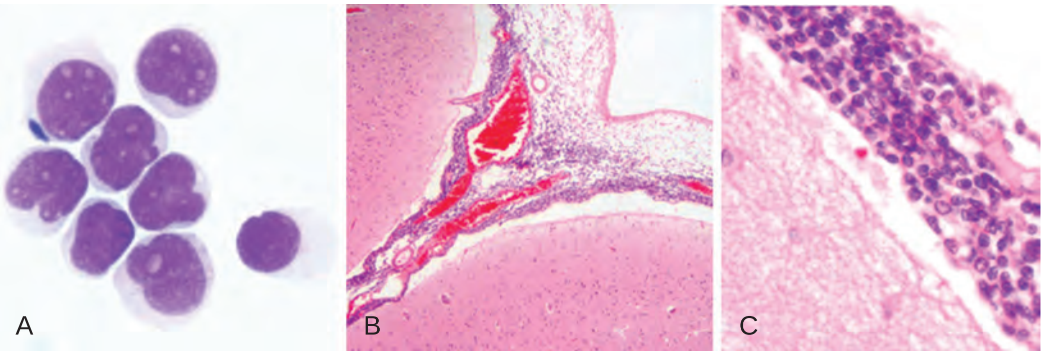

Figure 68.7 CEREBROSPINAL FLUID AND CENTRAL NERVOUS SYSTEM DISEASE. Blasts in the cerebrospinal fluid can be identified on a cytospin preparation. (A) They have similar cytologic features as the blasts in the blood or bone marrow aspirate. Histologic section of the brain is illustrated from a patient with acute lymphoblastic leukemia and leukemic meningitis. (B) The sections show blasts within the leptomeninges (higher power, C).

Induction therapy for ALL usually includes lumbar punctures with introduction of intrathecal chemotherapy during the first weeks of therapy. For those presenting with CNS disease at diagnosis or in whom CNS disease develops later in the course of the treatment, immediate intensified CNS treatment is imperative. These patients should receive intrathecal chemotherapy (intrathecal methotrexate alone or together with cytarabine and steroid [triple intrathecal therapy]) twice weekly until clearing of cerebrospinal fluid along with initiation of systemic chemotherapy. Cranial irradiation is often added for patients who present with active CNS involvement and may be delivered during postremission therapy.[35]

CNS prophylaxis is an essential component of therapy for all patients given the high incidence (30% to 40%) of CNS relapse if the CNS prophylaxis is omitted. Now with the universal adoption of CNS prophylaxis in the treatment regimens, the rates of CNS relapse have decreased substantially. CNS prophylaxis is typically administered by multiple rounds of intrathecal chemotherapy that are staggered over the entire treatment duration. In addition, the use of high-dose methotrexate and cytarabine also provides for CNS prophylaxis because both agents penetrate the blood-brain barrier. The intensive use of high-dose systemic methotrexate and frequent intrathecal therapy has often replaced the more traditional combination of CNS irradiation and intrathecal therapy that were the hallmarks of the earlier ALL regimens. This non-radiation-containing approach has resulted in effective CNS protection, with rates of CNS relapse now routinely reported as occurring in fewer than 5% to 10% of cases. Adolescents and young adults (AYAs) treated with pediatric regimens with more intensive CNS prophylaxis have reported CNS relapse rates as low as 1%. The addition of nelarabine to frontline therapy in children and young adults with T-ALL has improved EFS, largely as a result of decreasing CNS relapses.[35] The omission of cranial irradiation may prevent neurocognitive damage in adults. Although this has not been demonstrated in adult studies, definitive evidence from pediatric studies indicates that avoidance of cranial irradiation may prevent declines in cognitive function.[36]

MAINTENANCE THERAPY

The goal of maintenance treatment is to prevent disease relapse by elimination of leukemia clones by long-term exposure to cytotoxic drugs. One of the commonly used regimens uses daily 6-mercaptopurine and weekly oral methotrexate with monthly vincristine and prednisone (POMP regimen). Some groups replaced prednisone with dexamethasone. The duration of maintenance treatment is generally 2 to 3 years (2 years for women and 3 years for men). Similar to the other components of adult ALL regimens, the adoption of long-term maintenance therapy is based upon the benefit of maintenance therapy that has been demonstrated in pediatric trials.

Although the benefit of maintenance therapy in adult trials has not been demonstrated in randomized trials, it has been shown that omission of maintenance treatment leads to worse clinical outcomes. In an early CALGB study, 164 newly diagnosed ALL patients were randomized to receive daunorubicin or mitoxantrone during induction followed by four cycles of consolidation. No maintenance therapy was planned. There were significantly more relapses noted in this study, with median remission duration of only 10 to 12 months. The study was stopped earlier than planned because remission duration was shorter than in historical control participants who had received maintenance therapy. Similar results were obtained by the Dutch-Belgian Haemato-Oncology Cooperative Group (HOVON), which treated 130 ALL patients with induction followed by three cycles of consolidation. No maintenance therapy was given. The estimated 5-year OS and DFS were only 22% and 28%, respectively. Pediatric regimens routinely incorporate CNS prophylaxis during the maintenance phase. Pediatric studies have also reported favorable impact on DFS of achieving adequate myelosuppression with the chemotherapy drugs during the maintenance phase. Thus it appears that careful adjustment of the doses of the oral agents used during maintenance therapy to achieve optimal yet safe myelosuppression improves treatment outcomes, although the optimal duration of maintenance therapy varies from 2 to 3 years.[37]

ALLOGENEIC STEM CELL TRANSPLANT IN FIRST COMPLETE REMISSION

Despite attempts to improve DFS in adult ALL, OS with the standard chemotherapy regimens described earlier has been “fixed” at approximately 35% to 45% for the past decade. Over the years, the question of whether to recommend allogeneic transplant in first remission. A meta-analysis of seven studies (with 1274 patients) that prospectively assessed OS using genetic randomization based on donor availability reported significantly better OS in the donor group versus the no-donor groups (hazard ratio: 1.29; $P = .037$), which was more pronounced in patients with HR features.[38]

As treatment approaches and outcomes for adults with ALL have improved in the past 15 years, the role of allogeneic stem cell transplant is evolving. An intensive pediatric regimen administered to adult up to 40 years old was compared with registry data from the Center for International Blood and Marrow Transplant Research (CIBMTR) and demonstrated superior survival for chemotherapy versus transplant (3-year OS 77% vs. 53%, $P < .0001$).[39]

Importantly, the role of MRD has improved the ability to risk-stratify patients who might be most likely to benefit from allogeneic transplant in CR1. A number of more recent trials have demonstrated that patients with detectable MRD during postremission therapy have improved survival if they receive allogeneic transplant as postremission intensification.[11,20] In the GMALL study, MRD-positive patients who underwent allogeneic stem cell transplant had better OS than for those without allogeneic stem cell transplant (54% vs. 33%).[20] Thus detection of MRD in postremission therapy identifies patients who are at HR for relapse and may benefit from allogeneic transplant in CR1. Blinatumomab or other MRD “erasers” are now being used to eradicate MRD as a bridge to transplant and result in better outcomes following allogeneic transplant.[14]

Stem Cell Sources and Preparative Regimens for Allogeneic Stem Cell Transplantation

Matched sibling donors (MSDs) remain the preferred modality for the stem cell source undergoing allogeneic stem cell transplant; however, unrelated donor (URD) transplant outcomes have improved. For patients lacking an MSD, a matched URD (MUD) or an alternative donor source (e.g., umbilical cord blood [UCB]) should be pursued. In a CIBMTR registry study, outcomes of 1458 patients with ALL in CR1 who underwent URD transplants between 2000 and 2011 were analyzed. HLA 8/8 allele-matched URD recipients had similar transplant-related mortality (TRM) and all-cause mortality in comparison with related donor (RD) recipients. Seven of eight MUD recipients had a greater risk of TRM and all-cause mortality in comparison with RD recipients. The risk of TRM and all-cause mortality was also greater for 7/8 MUD recipients versus 8/8 MUD recipients. Compared with RD recipients, both 8/8 and 7/8 allogeneic stem cell transplant URD recipients had a lower risk of relapse. Both 8/8 and 7/8 MUD recipients had a greater risk of acute graft-versus-host disease (GVHD) and chronic GVHD in comparison with RD recipients.[40] The Minnesota group reported outcomes of myeloablative allogeneic stem cell transplant for ALL patients transplanted at their center and compared retrospectively the outcomes with respect to different donor sources. In an analysis restricted to 91 adult patients who received allogeneic stem cell transplant in CR1 or CR2 from 1990 to 2005, a difference between the allogeneic donor sources (matched related donor vs. MUD vs. UCB donor) was not observed for OS, DFS, or TRM. Similarly, in the ALL-SCT-BFM 2003 study of children and adolescents, a difference was not observed between matched related donor sources and at

TABLE 68.7 **Clinical Trials Evaluating Role of Myeloablative Allogeneic Stem Cell Transplant in Acute Lymphoblastic Leukemia**

Trial	Patients (*n*)	Age in Years, Median (Range)	Conditioning Regimen/Donor	TRM	DFS/OS	Comments
GOELALMO02[41]	41 (HR)	34 (15–52)	Etoposide/cyclophosphamide/TBI (12 Gy in six fractions) MSD	15%	DFS: 75% at 6 years; OS: 75% at 6 years	Showed improved survival with aSCT compared with ASCT
LALA 94[17]	100 (HR ALL excluding Ph$^+$ ALL)	33 (15–55) for the entire study cohort of 922 patients	Cyclophosphamide/TBI (10 Gy as a single dose or 12 Gy in six fractions) MRD	18% at 3 years	3-year DFS: 47%	For HR ALL, aSCT was superior to an ASCT
PETHEMA-93[25]	222 HR patient underwent MSD (if available); if not, randomized to ASCT vs. chemotherapy	27 (15–50)	Cyclophosphamide/TBI (12 Gy in six fractions) MSD		5-year OS: 35%	No benefit of an MSD transplant for HR patients (compared with ASCT or chemotherapy only approach)
MRC UKALLXII/ ECOG E2993[24]	Patients assigned to aSCT if an MSD available (donor group); those without donors randomized to ASCT vs. chemotherapy	15–64	Etoposide/TBI (13.2 Gy in six fractions) MSD	NRM HR (36% donor; 14% no-donor); SR (20% donor; 7% no donor)	5-year OS: HR (41% donor, 35% no donor) SR (62% donor vs. 52% donor)	Beneficial effect of all-SCT limited to SR group only; relapse rate decreased with aSCT in both HR and SR groups
HOVON[42]	ALL in CR1 according to sibling donor vs. no-donor comparison HR: 46 donor; 73 no donor SR: 50 donor; 88 no donor	Donor 31 (16–55)	Cyclophosphamide/TBI (12 Gy in six fractions) MRD	HR: NRM at 5 years (15% donor vs. 4% no-donor) SR: NRM at 5 years (16% donor vs. 2% no-donor, $P = .01$)	HR: OS at 5 years (53% donor vs. 41% no donor) SR: OS at 5 years (69% donor vs. 49% no donor, $P = .05$)	Similar to the MRC UKALLXII/ECOG E2993 trial, benefit of aSCT seems limited to SR patients

least 9 out of 10 matched MUD sources. Summary of these studies is presented in Table 68.7.

Because the majority of older adults are not candidates for a myeloablative allogeneic stem cell transplant, reduced-intensity conditioning (RIC) approaches have been explored in this patient population (Table 68.8). The Seattle group reported outcomes of allogeneic stem cell transplant using nonmyeloablative conditioning in 51 patients with ALL (median age: 56 years), half of whom were Ph positive. For the Ph-negative group, the 3-year OS for those transplanted in CR1 was 52%. However, the incidence of chronic GVHD was high, at 44%.[43] A registry study examined the efficacy of RIC in 93 ALL patients and compared it with 1428 ALL patients receiving myeloablative conditioning for allogeneic stem cell transplant using either a sibling or URD in CR1/CR2. Interestingly, the TRM at 3 years was similar between the RIC and myeloablative regimens (32% vs. 33%, respectively). The relapse rate at 3 years was slightly higher in the RIC arm, although this was not statistically significant (35% vs. 26%; $P = .08$). The OS at 3 years was similar between the two groups (38% for RIC arm vs. 43% for myeloablative arm, $P = .39$). This was a retrospective registry study; however, it provides evidence that RIC regimens can lead to similar survival in adults with ALL as an allogeneic stem cell transplant with a more intensive, myeloablative conditioning regimen. This is particularly compelling because the median age was significantly older for those receiving RIC (median age in RIC arm: 45 years vs. 28 years for myeloablative arm). The group from Minnesota has also reported encouraging results with UCB donor transplantation using a reduced-intensity conditioning (RIC) regimen. Eighteen adults (median age: 49 years; range: 24 to 68 years) with high-risk ALL (majority Ph ALL) received a UCB transplant using a RIC regimen and reported 3-year OS, TRM, and relapse rates of 49%, 28%, and 33%, respectively. Notably, patients in CR1 had a TRM of only 8% with no events after 6 months. These results with UCB donor transplantation are promising and compare favorably with conventional allogeneic stem cell transplant with relatively low TRM in this high-risk population.[44] Thus RIC-based allogeneic stem cell transplant regimens with alternative donor sources should be considered for older adults participating in prospective clinical trials.

In summary, allogeneic stem cell transplant is a curative option for patients with ALL and can be considered the standard recommendation for patients with a good performance status but with adverse disease risk factors in CR1. There have been significant improvements in transplantation techniques (better supportive care, refinement of preparative regimens, and uses of alternative donors as a source of stem cells) that are resulting in greater availability and improved transplant outcomes. At the same time, the TRM and mortality are significant, and allogeneic stem cell transplant has largely been offered to patients only younger than 60 years of age because of the poor tolerance of older adults to standard myeloablative transplant preparative regimens. Prospective incorporation of MRD evaluation may refine the ability to risk-stratify patients who are at HR of relapse and might benefit from allogeneic stem cell transplant in CR1. However, the benefit of an allogeneic stem cell transplant for MRD-positive

TABLE 68.8 Clinical Trials Evaluating Role of Reduced-Intensity Conditioning Allogeneic Stem Cell Transplant in Acute Lymphoblastic Leukemia

Trial	Number of Patients	Age in Years, Median (Range)	Conditioning Regimen/Donor	Mortality	DFS/OS	Comments
Arnold[45]	22 (11 Ph^{+})	38 (21–58)	Fludarabine/busulfan ± ATG MSD or MUD	TRM: 45%	Median survival: 354 days	High TRM of the group; all patients with aGVHD had CR indicating toward GVL effect

patients remains to be proven and has been studied only prospectively in a single study to date. Conversely, patients who were MRD negative in CR1 may best be treated by chemotherapy alone. Overall, the role of allogeneic stem cell transplant in CR1 merits further study, and it is important for these patients to participate in clinical trials exploring such approaches.

Autologous Stem Cell Transplantation

The role of autologous transplant for patients with ALL is controversial. ASCT in CR1 has also been studied prospectively in several clinical trials. Dhedin and colleagues reviewed the data from the French LALA 85, 87, and 94 trials and compared the outcomes of patients in CR1 who were randomized to chemotherapy versus ASCT. There was no improvement in DFS or OS with the use of ASCT compared with postremission chemotherapy, but there was a lower incidence of relapse at 10 years (66% vs. 78%; $P = .05$).[50] In the MRC UKALLXII/ECOG E2993 trial, 456 patients were randomized to chemotherapy versus ASCT in CR1. Patients randomized to chemotherapy had significantly better 5-year EFS (41% vs. 32%; $P = .02$) and OS (46% vs. 37%; $P = .03$).[24] Thus outside of a clinical trial, an ASCT cannot be recommended for ALL patients.

THERAPY FOR SPECIFIC DISEASE SUBSETS

Philadelphia Chromosome–Positive Acute Lymphoblastic Leukemia

The Ph chromosome [t(9;22)(q34;q11)] is the most common cytogenetic abnormality in adult ALL, and its incidence increases with age. Among patients older than 60 years, 40% to 50% have the Ph chromosome. Before the introduction of molecularly targeted therapy, Ph^{+} ALL was associated with lower remission rates and a very poor prognosis, with a median survival time of only approximately 9 months.

With the introduction of therapy using TKIs targeted to the aberrant BCR-ABL protein, the outcome of Ph^{+} ALL has improved substantially. Imatinib, the first targeted TKI developed for use in Ph leukemia, has been combined with multiagent chemotherapy by various groups, and this has substantially improved both CR rates and DFS (Table 68.9).

The MD Anderson group was the first to report on the successful combination of a targeted TKI, imatinib, to frontline chemotherapy (hyper-CVAD). The 3-year CR duration and OS rates were significantly superior in the hyper-CVAD–imatinib arm compared with historical control participants treated with hyper-CVAD alone (68% vs. 24% and 54% vs. 15%, respectively; $P < .001$).[51,52] The Japanese also reported impressive improvements compared with their control participants. In the JALSG ALL202 trial, imatinib, 600 mg/day, was added to standard induction followed by alternating cycles of high-dose methotrexate and high-dose cytarabine and single agent imatinib 600 mg/day. Later maintenance therapy with imatinib 600 mg/day with monthly vincristine and prednisone was given. After longer follow-up, they reported results on 103 patients with Ph^{+} ALL with a 97% CR rate and 3-year OS of 57%, both of which were significantly better than in historical control participants.[53,54]

Older adults with Ph^{+} ALL have also demonstrated improved survival with the addition of imatinib to reduced-intensity chemotherapy regimens. Ottmann and colleagues reported for the German study group in which older adults (>55 years of age) Ph^{+} ALL patients were randomized to receive induction cycle with imatinib alone ($n = 28$) versus combination chemotherapy ($n = 27$)[58]. The CR rate was 96% in the imatinib arm, which was significantly better than the CR rate of 50% in the chemotherapy alone arm. This was the first prospective randomized controlled trial comparing imatinib with chemotherapy and clearly showed the superiority of the imatinib arm.[58] The Italian GIMEMA group treated 30 Ph^{+} ALL patients (median age: 69 years; range: 61 to 83 years)

TABLE 68.9 Clinical Trials With Tyrosine Kinase Inhibitor Plus Chemotherapy for Adult Philadelphia Chromosome–Positive Acute Lymphoblastic Leukemia

Trial	Patients (*n*)	Age in Years, Median (Range)	CR Rate	Disease-Free Survival	Overall Survival	Comments
MDACC Hyper-CVAD Imatinib[51,52]	54	51 (17–84)	93%	68% at 3 years	In de novo patients 40 years of age or younger: 3-year OS was 90% with aSCT ($n = 10$) vs. 33% without aSCT ($n = 6$), $P = .05$	First report of the combination of chemotherapy with a TKI Imatinib 400 mg/day on days 1–14 of induction; 600 mg continuously during courses 2–8; 600 mg during 2 years of maintenance therapy with monthly vincristine–prednisone; then imatinib indefinitely; aSCT in CR1 as feasible
JALSG ALL202[53,54]	103	45 (15–64)	97%	For those younger than age 55 years, 54 of 74 patients in CR1 who had aSCT, only 13% relapsed; among the 20/74 patients in CR1 who did not undergo SCT, 90% relapsed	57% at 3 years For patients younger than age 55 years, OS at 3 years was 75.0% for the transplanted group vs. 36.4% for the nontransplanted group	Standard induction plus imatinib 600 mg/day followed by alternating cycles of high-dose methotrexate and high-dose cytarabine and imatinib 600 mg/day; imatinib 600 mg/day with monthly vincristine–prednisone for maintenance
GRAAPH-2003[55,56]	45	45 (16–59)	96%	43% at 4 years	52% at 4 years The 4-year OS in the aSCT, ASCT, and no SCT groups were 55%, 80%, and 25%, respectively	Imatinib was started with consolidation in good early responders (corticosensitive and chemosensitive ALL) or during the induction course in poor early responders
GMALL[57]	47 (alternating imatinib and chemotherapy)	46 (21–65)	NA because only CR patients were eligible	52% at 2 years	36% at 2 years	Coadministration of imatinib with induction cycle 2 led to CR rate of 95% and molecular CR rate of 52% of patients compared with 19% (significantly worse) in patients in the alternating treatment cohort
	45 (concurrent imatinib and chemotherapy starting after induction I)	41 (19–63)	95%	61% at 2 years	43% at 2 years	
GMALL[58]	28 (imatinib arm)	66 (54–79)	96%	30% at 1.5 years	57% at 1.5 years	Patients older than age 55 years with de novo ALL and not eligible for aSCT; randomized to single-agent imatinib induction vs. multiagent chemotherapy induction; subsequent consolidation or maintenance with imatinib plus chemotherapy for all patients
	27 (chemotherapy arm)	68 (58–78)	50% (significantly inferior to imatinib arm)	35% at 1.5 years	41% at 1.5 years	
GIMEMA[59]	29	69 (61–83)	100%	48% at 1 year	74% at 1 year	7-day steroid pretreatment followed by induction treatment with imatinib (800 mg/day) plus steroids
NILG protocol 09/00[60]	59	45 (20–66)	92%	39% at 5 years	38% at 5 years	Imatinib (600 mg/day) was added to each chemotherapy course for 7 consecutive days, starting from day 15 of chemotherapy course 1 and from 3 days before chemotherapy during courses 2 to 8

TABLE 68.9 **Clinical Trials With Tyrosine Kinase Inhibitor Plus Chemotherapy for Adult Philadelphia Chromosome–Positive Acute Lymphoblastic Leukemia—cont'd**

Trial	Patients (*n*)	Age in Years, Median (Range)	CR Rate	Disease-Free Survival	Overall Survival	Comments
UKALLXII/ ECOG2993[61]	175	Not reported	92%	54% at 3 years	42% at 3 years	Outcomes (CR, DFS, and OS) were significantly better compared with the historical preimatinib cohort; for the imatinib group, 3-year OS for patients who received aSCT was 59% vs. 28% for those who did not receive aSCT
PACE[62]	32 (relapsed/TKI intolerant)	62	41%	7% at 12 months	40% at 12 months	Ponatinib is active in Ph$^+$ ALL with T135I mutation
GIMEMA LAL1811[63]	44	68 (27–85)	95%		87.5% at 1 year	Mostly elderly patients. Only 1 death attributed to ponatinib
Ponatinib HyperCVAD[64]	86	46 (21–80)	100%	84% at 3 years	73% at 5 years	18 (21%) underwent aSCT in CR1. Trend for better OS in patients who did not undergo HSCT in first remission
Dasatinib Blinatumomab[65]	63	54 (24–82)		88% at 18 months	95% at 18 months	Complete molecular response increased from 29% with dasatinib to 60% after two cycles blinatumomab
EWALL-PH-02[66]	36	66	97%	89% at median follow-up of 7 months		
CALGB 10001[67]	58	45	8 patients converted from MMR to CMR after transplant	Median DFS 5.9 months after auto-HSCT	Median OS 4.8 years. 47% OS with allo-HSCT vs. 42% OS with auto-HSCT	TRM associated with ASCT occurred in one (5%) of 19 patients, while TRM associated with aSCT occurred in 3 (20%) of 15 patients

ALL, Acute lymphoblastic leukemia; *aSCT*, allogeneic stem cell transplantation; *ASCT*, autologous stem cell transplantation; *CMR*, complete molecular response; *CR*, complete remission; *CR1*, first complete remission; *DFS*, disease-free survival; *HSCT*, hematopoietic stem cell transplantation; *MMR*, major molecular response; *NA*, not applicable; *OS*, overall survival; *Ph$^+$*, Philadelphia chromosome positive; *SCT*, stem cell transplantation; *TKI*, tyrosine kinase inhibitor; *TRM*, treatment-related mortality.

with 7-day steroid pretreatment followed by induction treatment with only imatinib (800 mg/day) plus steroids. Impressively, all 29 evaluable patients achieved CR with 1-year DFS and OS of 48% and 74%, respectively.[59] These early studies demonstrated that TKI therapy is crucial and that the TKI should be started early during induction chemotherapy and continued throughout postremission and maintenance therapy and, potentially, indefinitely.

Despite these significant advances in the treatment of Ph$^+$ ALL, relapse remains a major challenge. Resistance to imatinib develops and most frequently results from the emergence of a resistant clone with ABL kinase domain mutations, most commonly the T315I mutation. These kinase domain mutations cause conformational changes in the ABL protein that prevent effective binding. Other potential mechanisms of resistance that have been described include reduced intracellular availability of imatinib and activation of alternative signaling pathways such as the Src-kinase pathways. Second-generation TKIs, dasatinib and nilotinib, are more potent kinase inhibitors and are also effective against many imatinib-resistant mutations (although not the T315I mutation). In addition, dasatinib has been shown to penetrate the CNS and thus may be particularly effective in Ph$^+$ ALL.

Dasatinib has been tested in several prospective trials for previously untreated Ph$^+$ ALL. MD Anderson Cancer Center investigators evaluated hyper-CVAD plus dasatinib in newly diagnosed Ph$^+$ ALL patients. The median age of the 35 patients studied was 53 years (range: 21 to 79 years); 94% achieved CR. Of the patients who achieved CR, 61% of patients achieved CMR, meaning that there was no detectable MRD using quantitative PCR for *BCR-ABL*. Later, the same group reported that 24% of patients underwent allogeneic stem cell transplant (16% in CR1; 8% CR2), and 3-year DFS and OS for the entire cohort were 49% and 62%, respectively.[68]

In the GIMEMA LAL1205 study, dasatinib monotherapy (70 mg twice daily) with steroids was investigated for frontline treatment of 53 adult Ph$^+$ ALL patients (median age: 54 years). All patients achieved a complete hematologic response, and there were no induction deaths. Allogeneic stem cell transplant in CR1 was performed in 18 (34%) patients. At 20 months, the OS was 69% and DFS was 51%. BCR-ABL levels of less than 0.001% at day 85 correlated with DFS. These results with dasatinib without any cytotoxic chemotherapy are encouraging but demonstrated that single-agent dasatinib is not sufficient to cure this disease[69]. In a subsequent trial, the GIMEMA LAL1509, if patients did not achieve complete molecular response after a prolonged 84-day induction with dasatinib and steroids, they received more intensive combination chemotherapy and/or allogeneic stem cell transplant. At day 85, 58 out of 60 (97%) patients achieved a complete hematologic remission; however, only 11 (18.6%) patients achieved a CMR with TKI plus steroid induction, suggesting that dasatinib and steroids are insufficient to achieve a molecular remission in most patients and that additional postremission intensification is needed. Using this stratified treatment approach, the DFS was 62% with 18 months of follow-up and OS was 69%.[70]

Nilotinib is also a second-generation TKI that has been evaluated as frontline therapy. In a prospective, single arm phase II trial, induction treatment consisted of vincristine, daunorubicin, oral prednisolone, and nilotinib (400 mg orally twice daily). Patients in CR received either five courses of consolidation followed by 2-year maintenance therapy or an allogeneic stem cell transplant, depending on donor availability. More than 70% of patients received an allogeneic stem cell transplant. Estimated DFS and OS at 2 years were 71% and 66%, respectively, similar to rates observed with other TKIs.[66] Although these results are similar to other studies with dasatinib, most of the current trials in Ph$^+$ ALL have incorporated dasatinib in the frontline therapy because of its potential advantage over nilotinib with respect to CNS penetration.

Ponatinib is a third-generation ABL kinase inhibitor that maintains ABL kinase inhibitory effects even in the presence of the T315I mutant kinase, which has been the most commonly occurring mutation at time of relapse in Ph ALL, and is approved for relapsed disease based on data from the PACE trial.[62] In the chronic myeloid leukemia blast phase/Ph$^+$ ALL cohort, 37% (11 out of 30) of patients who were resistant or intolerant to second-generation TKIs and 27% (6 out of 22) of patients with T315I mutations achieved a major hematologic remission.

Ponatinib has also been studied for frontline treatment of Ph$^+$ ALL, both in combination with intensive chemotherapy and in combination with low dose chemotherapy. In a study investigating ponatinib combined with hyper-CVAD, 45 mg was given daily for the first 14 days of cycle 1 and then continuously for the subsequent cycles.[64] The CMR rate was 84%. The estimated 5-year continuous CR, EFS, and OS rates were 84%, 68%, and 73%, respectively. Two patients experienced ponatinib-related deaths from myocardial infarction. Therefore, due to concern for vascular toxicity associated with long-term use of high-dose ponatinib, the protocol was amended to reduce ponatinib to 30 mg daily starting at cycle 2, with further reduction to 15 mg once a CMR was achieved. In a propensity score analysis, ponatinib hyper-CVAD therapy was superior to the historical control dasatinib and hyper-CVAD. The 3-year EFS rates for ponatinib hyper-CVAD and dasatinib hyper-CVAD were 69% and 46%, respectively, and the 3-year OS rates were 83% and 56%, respectively.[71] Using ponatinib with minimal chemotherapy, the GIMEMA LAL1811 investigated ponatinib with steroids (without allogeneic transplant) in untreated older adults with Ph$^+$ ALL patients. Steroids were administered from day −14 to day 29 during course 1. Despite this being an older population that may have cardiovascular comorbidities, patients received ponatinib 45 mg daily for eight consecutive courses of 6 weeks. Only one death on study was attributed to ponatinib. Ninety-five percent of patients achieved CR after course 1. Sixty percent of evaluable patients were in CMR at 24 weeks (end of course 4). OS was 87.5% at 1 year follow-up. Although the rate of CMR in this study clearly exceeds those of prior dasatinib and steroids studies, longer-term follow-up is necessary to determine if patients can safely receive high-dose ponatinib for 48 weeks and if this results in meaningful improvement in OS.[63] Further definition of the incidence of serious vascular events with ponatinib in the frontline treatment setting of Ph ALL is required with longer-term follow-up of these studies. However, these studies have demonstrated high rates of CMR compared with other TKIs, and ponatinib is being used increasingly in the frontline treatment of Ph$^+$ ALL.

Recently immunotherapies have been added to TKIs in Ph$^+$ ALL as another approach to minimize toxicity and enhance response rates. In the first effort to investigate this approach, blinatumomab (a CD19 bispecific T-cell engager [BITE]) was added following dasatinib and prednisone induction. High CMR rates were achieved, and with a median follow-up of 18 months, OS was 95% and DFS was 88%. The regimen was well tolerated, with fever, neutropenia, and cytomegalovirus (CMV) reactivation being most common adverse events.[65] Based on these exciting results with a second-generation TKI, studies are underway that evaluate ponatinib and blinatumomab with low-intensity chemotherapy in newly diagnosed Ph ALL.

Role of Transplantation for Philadelphia Chromosome–Positive ALL in the Era of Tyrosine Kinase Inhibitor–Based Therapy

Allogeneic stem cell transplant in CR1 was the only curative treatment option for Ph$^+$ ALL in the pre-TKI era. Although the addition of TKI therapy has significantly improved the outcome of Ph$^+$ ALL, many recent studies have also highlighted the continued role of allogeneic stem cell transplant for Ph$^+$ ALL for eligible patients, at least when a first or second generation TKI is used.[67,72] In a landmark analysis, in patients under 60 years of age who received allogeneic transplant following intensive chemotherapy with dasatinib, allogeneic transplant showed statistically significant improvements in RFS and OS compared with those who were not transplanted in CR1 with 12 month OS of 87% in the transplanted group.[73] Potentially the use of a third-generation TKI and/or of frontline immunotherapy with TKI will obviate the recommendation for allogeneic transplant. In the hyper-CVAD with ponatinib study mentioned previously, the 3-year OS rate was 66% for patients who underwent allogeneic stem cell transplant and 90% for patients who did not undergo allogeneic stem cell transplant; however, this was not statistically significant.[64]

The role of autologous transplantation for Ph$^+$ ALL has also been explored and remains uncertain as the field advances with new TKIs and immunotherapies.[67,72] In a study of 64 adults with a median age of 60 years, dasatinib with dexamethasone induction followed by allogeneic, autologous, or continued chemotherapy with TKI yielded similar 3-year survival approaches; however, patients with the P210 isoform had poor outcome.[72] Finally, the role and duration of TKI therapy after intensive chemotherapy and transplant is currently an area of active investigation. Currently, it appears that continuing TKI therapy indefinitely for those patients receiving chemotherapy alone and for a minimum of 1 to 2 years after transplant is an appropriate strategy.[74] Studies evaluating MRD may provide guidance with the question of duration of posttransplant TKI therapy.

In summary, during the past two decades the addition of TKIs to combination chemotherapy has resulted in significant improvement in DFS and OS for both younger and older adults with Ph$^+$ ALL. High CMR rates can now be achieved and have been demonstrated to be associated with improved outcomes. While allogeneic stem cell transplant remains the current treatment of choice for eligible patients, the next generation of studies in Ph$^+$ ALL may help to define the role of transplantation when CMRs are achieved with combination TKI and chemotherapy alone.

Burkitt Lymphoma/Leukemia

Burkitt lymphoma (BL) is a mature B-cell lymphoma with an extremely short doubling time that often presents in extranodal sites or as acute leukemia. Thus a brief description of the therapy is warranted in this chapter. Morphologically (Fig. 68.8), the malignant cells are intermediate in size, have round nuclei with small nucleoli, are intensely basophilic, and frequently have vacuolated cytoplasm. In a BM biopsy and in tissue sections, the tumor is classically described as having a “starry sky” appearance because of the presence of multiple tingible body macrophages with phagocytized cellular debris. Immunophenotypically, the tumor cells express moderate to strong levels of surface IgM with light chain restriction, indicating origin of the tumor from a mature B cell. The tumor cells also universally express the B-cell antigens CD19 and CD20 and germinal center–associated markers such as CD10 and BCL6. Unlike B-ALL, BL cells do not express CD34 or TdT. The genetic basis of the disease is the underlying MYC translocation at band 8q24 to either the Ig heavy chain region on chromosome 14 or less commonly at the lambda (22q11) or kappa (2p12) loci.

Prompt diagnosis and recognition of this entity are essential because this is now a highly curable leukemia (in the range of 65% to 80% in recent trials); however, failure to institute appropriate therapy at diagnosis for BL results in emergence of early resistance and

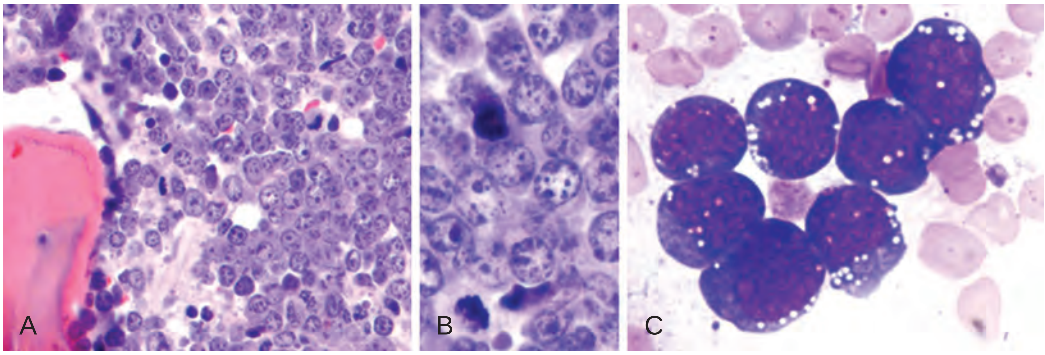

Figure 68.8 BURKITT LEUKEMIA/LYMPHOMA (A–C). Bone marrow biopsy and aspirate features of Burkitt leukemia/lymphoma are illustrated. The bone marrow (or lymph node) will show sheets of highly proliferating intermediate-sized neoplastic cells with a syncytial appearance. The cells are monotonous but have a stippled intermediate chromatin pattern with multiple small nucleoli. (C) On the aspirate, the Burkitt cells have an intermediate size, a denser chromatin than lymphoblasts, and deeply blue cytoplasm with prominent vacuoles.

dismal outcomes. Traditional CHOP (cyclophosphamide, hydroxydaunomycin, vincristine [Oncovin], and prednisone) chemotherapy is inadequate and should not be used. Treatment should be initiated quickly and consists of aggressive combination chemotherapy with CNS prophylaxis. These patients are at HR for the development of tumor lysis syndrome; therefore aggressive hydration and administration of allopurinol and/or rasburicase is important. All current regimens rely on short intensive courses of chemotherapy that incorporate fractionated doses of alkylating agents, high doses of methotrexate and cytarabine, and intensive intrathecal prophylaxis. In the United States, commonly used regimens include CODOX-M/IVAC (cyclophosphamide, vincristine, doxorubicin, high-dose methotrexate/ifosfamide, etoposide, and high-dose cytarabine) CALGB 9251, and hyper-CVAD. With these regimens, approximately 80% achieve CR, and 2-year survival is approximately 60% to 70%. In the CALGB 9251 trial, 52% of the patients were alive and in continuous CR at a median follow-up of 5.1 years. Because BL has a predisposition for CNS involvement, aggressive CNS-directed therapy is essential and typically consists of intrathecal administration of methotrexate, cytarabine, and hydrocortisone. Recurrence after the first 2 years rarely occurs; therefore maintenance therapy has not been shown to be beneficial and is not recommended.

Because of the strong expression of CD20 in mature B-cell ALL, several groups have incorporated rituximab into the frontline chemotherapy regimen, with impressive further improvements in survival. The hyper-CVAD–rituximab regimen was reported in 31 patients with newly diagnosed BL, with a CR rate of 86% and a 3-year survival rate of 89%. Similarly, the addition of rituximab to the treatment in both the GMALL and CALGB regimens has proven feasible with OS of 91% (3 years) and 79% (2 years), respectively. Based on these exciting improvements in survival, the addition of anti-CD20 targeting to frontline therapies for BL is now considered the standard of care.

ADOLESCENTS AND YOUNG ADULTS WITH ACUTE LYMPHOBLASTIC LEUKEMIA: THE INTERSECTION BETWEEN PEDIATRIC AND ADULT CARE

Evaluation of the outcomes of young adult patients, here defined as patients between the ages of 15 and 39 years, presents specific challenges. Because of community referral patterns, these patients may be treated by either pediatric or adult oncologists. As such, the treating physician may view a patient in this age group either as an older child or as a younger adult. The oncologist will choose a regimen most appropriate for the population usually seen by that particular physician. A number of retrospective comparisons of the clinical outcome of adolescents enrolled on adult and pediatric clinical trials have resulted in interesting observations about what that appropriate treatment regimen should be and have guided the design of a number of prospective clinical trials designed specifically for AYAs with ALL and typically include patients from 15 to 39 years of age. The majority of these retrospective comparison studies demonstrated a significant survival advantage for AYA patients treated by the pediatric versus the adult cooperative group.[75] Although the specific treatment approaches differ among countries, several treatment themes have emerged as being potentially important. Pediatric studies throughout the world use considerably more treatment with nonmyelosuppressive drugs, including glucocorticoids (both dexamethasone and prednisone), vincristine, and L-asparaginase. CNS prophylaxis is typically administered earlier, with a greater frequency, and for a more prolonged period during pediatric group trials. Finally, long-term maintenance therapy was also continued for a longer period in pediatric cooperative group trials. Based on additional retrospective data from Finland and the MD Anderson Cancer Center, it appears that treating patients in a uniform fashion by an experienced group of physicians and nurses is also a very important component in the successful treatment of young adults with ALL.

To address the many unanswered questions that have been raised by the retrospective comparison trials and to determine whether AYA patients treated by adult hematologists and oncologists can achieve similarly improved outcomes to the pediatricians for this age group, prospective cooperative group trials have been conducted in North America and in Europe and validate the results of retrospective studies—AYAs fare better with intensive pediatric regimens, and several of these trials[76–78] are summarized in Table 68.10 and additionally reviewed in reference 75. A few important points about these prospective studies can be made. (1) Use of a pediatric regimen is feasible and results in low treatment related mortality of less than 5%; however, morbidity and mortality rates increase over age 45 to 50 years, limiting the exact use of these regimens in older adults. (2) EFS and OS are significantly improved compared with historical controls, with survival rates routinely now greater than 70% for both B- and T-cell ALL. (3) Outcomes were equivalent for both B- and T-cell ALL. (4) Achievement of MRD negativity in early treatment is the most important prognosticator of DFS and may inform design of future clinical trials. The design and the results of the Nordic Society of Pediatric Hematology and Oncology (NOPHO) ALL2008 highlight some of these important issues.[78] This was the first study of newly diagnosed Ph-negative B- and T-ALL patients that treated all patients ages 1 to 45 years on a single risk-adapted protocol. They reported a 4-year EFS of 84% in those aged 16 to 39 years, which is superior to both the Dana Farber Cancer Institute and CALGB results. Their protocol was less intensive during induction and therapy for those with SR but had more intensive postremission therapy for those with higher risk, largely defined by MRD status at the end of induction. This illustrates a remarkable effort to successfully perform an innovative protocol that aimed to coordinate care of children, AYAs using rigorous monitoring and strong centralized support to facilitate treatment adherence.

TABLE 68.10 Outcomes of Adolescent and Young Adult Patients Treated With Pediatric Intensive Regimens: Several Examples of Recent Trials

	ALL-96 (PETHEMA)[79]	DFCI Adult ALL 01–175 [76]	CALGB 10403 (NCTN)[77]
Patient Population			
Patients (*n*)	81	92	318
Median age (range)	20 years (15–30)	28 years (18–50)	24 years (17–39)
Gender	Male: 62%	Male: 61%	Male: 61%
Immunophenotype	Precursor B- and T-ALL	Precursor B- and T-ALL	Precursor B- and T-ALL
Outcomes			
EFS	61% (6 year)	58% (4 year)	66% (2 year)
OS	69% (6 year)	67% (4 year)	78% (2 year)

ALL, Acute lymphoblastic leukemia; *EFS*, event-free survival; *OS*, overall survival.

While these prospective trials demonstrate that an intensive pediatric regimen results in improved survival rates for AYAs, many challenges remain to ensure access to care, to minimize treatment toxicity, and to develop and follow specific survivorship monitoring plans. As stated previously, the successful outcome of a patient with ALL is, largely, based on the ability of both the medical team and the patient to adhere to the rigorous and lengthy regimens that currently remain the gold standard of care. The next generation of studies, linked to important biologic, psychosocial, and pharmacologic correlates, will result in further insights into optimizing the comprehensive approach to treatment and follow-up for this significant group of patients with ALL and may be the next step to achieving the high cure rate and successful transition back to "normal" life now routinely achieved in children with ALL. In particular, due to significant pharmacogenomic variability and age-related changes in drug metabolism, further evaluation and potential dose modifications of some of the agents, including glucocorticoids, vincristine, and asparaginase, crucial to the successful outcomes of children, will need to be addressed in future studies of AYA and older adults with ALL, to optimize these regimens for these populations. Enrollment in clinical trials, which has led to the survival rates now approaching more than 90% in pediatric ALL, will be the key to making progress in survival rates for both younger and older adults with ALL.

Differences in Treatment for B- Versus T-Cell Acute Lymphoblastic Leukemia

To date, different phenotypes of ALL (Ph-negative B-ALL and T-ALL) have been treated with the same management approach, as described earlier. Aforementioned studies have also elucidated whether there are outcome differences based on immunophenotype, and what implications this may have on future therapy development as our understanding of the underlying biology evolves.

The Children's Oncology Group (COG) AALL0434 study enrolled exclusively T-ALL patients aged 1 to 31 and showed improved DFS when nelarabine was added to an augmented BFM regimen with a 4-year DFS of 88.9% as compared with 83.3% without nelarabine,[80] largely as a result of reduction in the number of CNS relapses. This has not yet been prospectively tested in adults older than the age of 30 years, but given these encouraging results, it is possible that future treatment of T-ALL will incorporate nelarabine into frontline therapy, similar to what was done in the COG study.

Emerging data on differences in the molecular genetic underpinnings of T- versus B-ALL and the heterogeneity within each of these subsets will undoubtedly lead to more individualized "targeted" approaches (see Novel Therapies later). As these new approaches are incorporated into novel frontline treatment trials, it may be possible to eradicate resistant subclones that give rise to relapse and result in higher survival rates.

Comparison of Pediatric-Inspired Regimens With Allogeneic Transplant for Adolescents and Young Adults

Given these very encouraging improvements in outcome for AYAs with ALL using intensified pediatric regimens, the role of allogeneic stem cell transplant in CR1 has been reexamined in two retrospective comparison studies[81,82]. These investigators reported significantly better outcomes for patients receiving the intensive pediatric approaches compared with transplant. Overall, treatment using a pediatric-inspired regimen for young adults with ALL appears to result in significantly improved survival compared with allogeneic stem cell transplant in CR1. Similarly, data from the GRAALL pediatric-inspired protocols showed that there was no difference in relapse, nonrelapse mortality, or RFS overall in patients who went onto allogeneic stem cell transplant compared with those who did not undergo transplant.[18] However, allogeneic stem cell transplant did result in a longer RFS in patients who were MRD positive after induction chemotherapy, suggesting there is a select HR group of patients who still benefit from transplant.

OLDER ADULTS WITH ACUTE LYMPHOBLASTIC LEUKEMIA

Older adults (generally defined as older than 60 years old) constitute a challenging subset of ALL patients. They have a worse prognosis as compared with their younger counterparts. Most studies demonstrate that adults older than 60 years old have survival rates below 15%. Various factors contribute to the poor outcome of these patients, both patient related (e.g., the presence of comorbidities, less likely to be eligible for allogeneic stem cell transplant, poor tolerance of intensive chemotherapies) and disease related (more likely to have unfavorable disease characteristics such as the presence of the Ph chromosome, complex karyotype, and genetic alterations such as TP53 and IKZF1 mutations). It is important to note that many large clinical trials have excluded patients older than 60 years of age; therefore clinical outcome data for this group are sparse. In historical trials, although CR rates for older adults range from 60% to75% with traditional intensive combination therapies, due to treatment-related complications and disease resistance, OS at 3 to 5 years has been poor, with fewer than 15% to 20% achieving long-term survival (for review and analysis, see Reference 83).

One of the major problems with application of traditional BFM therapies in older adults has been the unacceptable toxicity from the key agents—asparaginase, prednisone/dexamethasone, and vincristine. The GMALL successfully introduced dose-reduced PEG asparaginase 500 IU/m^2 in postinduction phases and has reported on its safety and encouraging results in patients 75 years old or younger.[84] A modified protocol based on the DFCI ALL regimen was applied to older patients with ALL (older than 50 years old). The study met the primary end point, with a 1-year OS of 63%. However, the administration of the standard dose PEG asparaginase 2000 IU/m^2 resulted in a high rate of hyperbilirubinemia, and this led to amending the PEG asparaginase dose twice during the study course, down to only 500 IU/m^2. In a smaller study of a modified pediatric regimen in adults up to the age 70 years (median = 46 years), therapeutic drug monitoring of asparaginase levels was used to optimize dosing of asparaginase, a dose of 1000u/m^2 resulted in therapeutic levels in all patients and 3-year EFS of 54%.[85,86] These studies suggest that it may be possible to modify intensive pediatric regimens with some reduction in toxicity; however, new approaches may be changing the treatment paradigm for older adults.

Given the poor prognosis of older adults with ALL and difficulty tolerating intensive chemotherapy regimens, other studies are also investigating the use of the immunotherapies blinatumomab or inotuzumab ozogamicin, which are approved for relapsed disease, in the frontline setting with or without reduced intensity chemotherapy. These new trials result in high CR rates and improved EFS in early studies with limited long-term follow-up. The MD Anderson group used inotuzumab ozogamicin in frontline therapy to allow combination with reduced-intensity chemotherapy in frontline treatment of adults 60 years old or older with ALL. Patients received mini-hyper-CVD (cyclophosphamide and dexamethasone at 50% dose reduction, no anthracycline) for up to eight cycles. Median age was 68 years, and notably 41% of patients had a p53 mutation. Ninety-eight percent of patients achieved a CR, CRp (complete remission with incomplete platelet recovery), or CRi (complete remission with incomplete hematologic recovery), and 80% of these patients were MRD negative after the first cycle. No early deaths were reported. The 4-year continuous remission and OS rates were 78% and 50%, respectively. However, 4-year OS was only 34% in patients 70 years old or older, which was attributed to higher rates of infection and therapy-related MDS or AML. To decrease treatment-related mortality, the protocol has been amended to eliminate chemotherapy for patients 70 years of age or older. In addition, 4-year OS was only 22% in patients with HR cytogenetic abnormalities; additional studies are warranted.[87] The Southwest Oncology Group (SWOG) 1318 clinical trial studied blinatumomab as a single agent in newly diagnosed Ph$^-$ ALL, as well as in combination with dasatinib in Ph$^+$ ALL, in patients older than 65 years old. Patients received up to five cycles of blinatumomab followed by 18 months of POMP maintenance chemotherapy.[88] Among the Ph$^-$ patients, the median age was 75 years old and no patients died during the first 28 days of induction. Sixty-six percent of patients achieved a CR or CRi with single agent blinatumomab induction. At 1 year the DFS was 56% and OS was 65%.[77] The regimen was well tolerated and resulted in a 3-year OS of 34%. Additional ongoing studies both in Europe and in the United States are taking this approach one step further to evaluate the use of the new antibodies to eliminate entirely standard chemotherapy in older adults with ALL; the results of these trials are eagerly awaited. Consideration should be given to enrollment of older adults into these new frontline clinical trials, given the lack of progress with dose intensification of traditional agents and interest in reduced chemotherapy and addition of immunotherapies. Management of older adult patients with Ph$^+$ ALL is discussed in the Ph$^+$ ALL section; the incorporation of TKIs into frontline therapy has already made significant improvements in DFS for these high-risk patients.

RELAPSED ACUTE LYMPHOBLASTIC LEUKEMIA

As described earlier, with standard therapies for ALL, long-term DFS is only approximately 30% to 40%. Thus the majority of patients with ALL relapse despite the administration of postremission treatment. Until recently postrelapse therapies have resulted in CR2 in 30% to 40% of patients with a 5-year OS of only approximately 10%.[89–91] However, new immune-targeting approaches have revolutionized the approach to relapsed B-ALL and are resulting in high CR rates of 60% to 80% in patients with relapsed disease. An allogeneic stem cell transplant is still considered the standard potentially curative approach for all eligible patients in CR2 and beyond.

Vincristine is an important component of ALL treatment. In preclinical models, encapsulation of vincristine into sphingomyelin liposomes or “sphingosomes” has been shown to lead to increased efficacy without increased neurotoxicity compared with conventional vincristine. Sphingosomal vincristine administered every 2 weeks in relapsed or refractory ALL reported an overall response rate of 14%. A weekly schedule resulted in a higher CR rate of 19% overall and 29% in first salvage treatment.[92] Based on an improved toxicity profile and comparable efficacy in relapsed/refractory (RR) ALL, particularly as a single agent, in 2012 the FDA approved vincristine sulfate liposome injection (VSLI) for the treatment of adult patients with Ph-negative ALL in second or greater relapse or whose disease has progressed following two or more antileukemia therapies. However, with the advent of the targeted approaches described later, remission rates are now much higher for relapsed B-ALL.

Blinatumomab is a novel BITE antibody targeted against CD3 on T cells and CD19 on leukemia B cells. When blinatumomab concurrently binds CD3 and CD19, the T cells are activated and directed to CD19-expressing target B cells, resulting in a cytotoxic T-cell response. A pivotal phase III study of blinatumomab compared with chemotherapy that randomized patients with relapsed CD19$^+$ ALL in a 2:1 fashion. Blinatumomab demonstrated higher rates of CR, CRp, or CRi (44%) compared with chemotherapy (25%).[93] The study met its primary end point and confirmed median OS was significantly improved to 7.7 months in the blinatumomab group compared with 4.0 months in the chemotherapy group. Treatment with blinatumomab also resulted in a higher EFS than that with chemotherapy (6-month estimates, 31% vs. 12%). The unique side effects of blinatumomab that require special attention are cytokine release syndrome (CRS) and neurologic toxicity. Grade 3 or higher CRS and neurologic events occurred in only 5% and 9%, respectively, of patients. Eighty-eight percent of all CR/CRh responders achieved MRD negativity.[93,94] The FDA approval for blinatumomab also includes Ph$^+$ ALL. Another targeted approach is inotuzumab ozogamicin, which is a humanized anti-CD22 monoclonal antibody conjugated to calicheamicin, a cytotoxic antibiotic agent. Upon binding CD22 on the B-ALL blast surface, inotuzumab ozogamicin is rapidly internalized, and the link between the antibody and calicheamicin is cleaved, releasing calicheamicin into the cell. Calicheamicin binds to the minor groove of DNA and thus induces double-strand cleavage and subsequent apoptosis. A phase III trial randomized patients with Ph$^+$ and Ph$^-$ ALL in first or second relapse to receive inotuzumab ozogamicin or standard salvage chemotherapy.[95] The CR rate was significantly higher with inotuzumab ozogamicin with chemotherapy (81% vs. 29%). For those who achieved CR, 78% achieved MRD-negative response with inotuzumab ozogamicin, compared with only 28% with chemotherapy. Although PFS and OS with inotuzumab ozogamicin did improve upon chemotherapy, they were still unfortunately limited (5 months vs. 1.8 months, and 7.7 months vs. 6.7 months, respectively). The most serious nonhematologic adverse events with inotuzumab ozogamicin were liver-related. Venoocclusive liver disease of any grade occurred in 15 patients (11%) who received inotuzumab ozogamicin and in 1 patient (1%) who received standard therapy. Based on these results, inotuzumab ozogamicin was FDA approved for Ph$^+$ and Ph$^-$ B-ALL in 2017. Thus, although both blinatumomab and inotuzumab can result in high CR rates, remission duration is short and additional therapy such as allogeneic transplant still must be considered once remissions are achieved.

The newest approach to relapsed B-ALL is the approval of chimeric antigen receptor (CAR)-T cells which are genetically modified T cells that express antigen-binding moieties and T-cell activation domains. The basic structure of modern CARs includes an extracellular antigen binding domain, an intracellular T-cell signaling domain, and one or two intracellular T-cell costimulatory domains. The costimulatory domains play an important role in CAR-T-cell persistence. Two products for CD19$^+$ ALL have now been approved: one for children and young adults up to age 25 and one for adults with relapsed B-ALL. Tisagenlecleucel (formerly CTL019) is an anti-CD19 CAR-T-cell therapy that was investigated in a phase II study in children and young adults up to the age of 25 years with RR B-ALL.[96] Sixty-one percent of patients had relapsed after prior allogeneic stem cell transplant. The overall remission rate within 3 months was 81%, with all patients who had a response to treatment found to be negative for MRD. The rates of EFS and OS were 50% and 76%, respectively, at 12 months. The median duration of remission was not reached. Persistence of tisagenlecleucel in the blood was observed for as long as 20 months. In adults, KTE-X19 (brexucabtagene autoleucel) was approved in 2021 based on the results of a phase II trial of 71 patients with relapsed CD10$^+$ ALL and resulted in a 71% CR/CRi rate with a median relapse-free survival of 11.6 months and OS of 18.2 months (not reached among responders); 97% of responding patients achieved MRD-negative status.[97] Although CAR-T cells are highly effective in disease eradication, they are also associated with complicated toxicities, including serious CRS and neurologic toxicities, that require oversight in specialized medical centers. Severe neurologic events occurred more frequently in patients with higher-grade CRS. The requirement for allogeneic transplant for long-term survival following CAR-T-cell therapy–induced remissions remains an open question. New approaches to CAR-T therapy are evolving rapidly and are discussed briefly in the novel therapy section later.

The targeted antibody approaches have not yet been developed for T-ALL, although efforts are ongoing. To date, the only approved agent in adults with relapsed T-ALL is nelarabine, a prodrug that is demethylated by adenosine deaminase to the deoxyguanosine analog (ara-G). T lymphoblasts are sensitive to the cytotoxic effects of nelarabine. In the study that resulted in approval of nelarabine, 26 patients with relapsed T-ALL (age range: 16 to 66 years) were treated. The CR rate was 31%, with a 1-year OS of 28%. Neurotoxicity was seen in many patients.[98] Nelarabine is currently approved in the United States for both pediatric and adult patients with T-cell ALL and T-cell lymphoblastic lymphoma who have failed at least two chemotherapeutic regimens.

Despite the approval of these new agents, patients with relapsed ALL continue to be a challenging subgroup of patients, in particular because the duration of response is limited to months. Importantly, these agents approved for RR ALL are now entering trials in the frontline setting, with the hope that they will decrease relapse rates, obviate the need for rescue therapy, and improve OS in ALL.

NOVEL THERAPIES

Immunotherapy

Novel Chimeric Antigen Receptor T-Cell Therapies

Potentially one of the most exciting breakthroughs in ALL therapy is the development and results from trials evaluating CAR-T cells (Table 68.11). Two CD19 CAR-T-cell products are now FDA approved for relapsed disease as described earlier. One of the challenges of multiple CD19-directed immunotherapies such as blinatumomab, tisagenlecleucel, and brexucabtagene autoleucel is the occurrence of relapse with CD19-negative disease, or antigen escape by the ALL. Several research groups are developing bispecific CAR-T cells to concurrently target CD19 and CD22, or other antigens such as CD20, to mitigate this risk. A CD19 and CD22 bivalent CAR with a 41BB costimulatory domain in a phase I trial in pediatric and adult RR ALL and DLCBL has been published, reporting good tolerability and high MRD-negative CR rates (88% of the 100% of CR patients) for patients with B-ALL[99]; however, CD19-negative relapses still occurred that were not “salvaged” by the CD22 target. This and other early-phase dual targeting CAR-T-cell trials highlight the ongoing challenges of engineering multispecific CAR-T cells with equivalent potency across targets.

Another focus of CAR-T-cell research is allogeneic products that may help to shorten the time to treatment that is required for apheresis and manufacturing of autologous products. UCART22 is an example of a genetically modified T-cell product manufactured from non-HLA-matched healthy donor cells. Donor-derived T-cells are transduced using a lentiviral vector to express anti-CD22 CAR (anti-CD22 scFv-41BB-CD3ζ) and are further modified to disrupt the T-cell receptor alpha constant (TRAC) and CD52 genes. These modifications minimize the risk of GVHD and allow the use of anti-CD52–directed drugs following a lymphodepleting chemotherapy regimen.[100] Another area of intense interest is development of CAR-T-cell therapy directed to T-ALL, which poses a particular challenge due to the very real risk of host-engineered T-cells killing themselves, known as “fratricide.” Significant engineering has taken place using CRISPR (clustered regularly interspaced short palindromic repeats) and other techniques to avoid these issues, and the early CD7 CAR-T-cell trials are now being reported with promising early results in patients with highly refractory disease T-ALL.[101]

Daratumumab

As discussed earlier, therapy for relapsed T-ALL remains an unmet need. CD38 is a type II transmembrane glycoprotein expressed on immature T and B lymphocytes, natural killer (NK) cells, activated T cells, plasma cells, monocytes, and red blood cells. CD38 is strongly expressed by B- and T-ALL blasts. Daratumumab is a human IgG1 κ monoclonal antibody that binds CD38 and has been demonstrated to be safe and effective in patients with multiple myeloma. Daratumumab demonstrated efficacy in vitro and in vivo in T-ALL xenograft models.[102] Furthermore, daratumumab cleared MRD in T-ALL xenograft models as a single agent and when used in combination with chemotherapy. The degree of CD38 expression on cells did not correlate with daratumumab response. Finally, recent case reports demonstrated daratumumab efficacy in several T-ALL patients with RR MRD after allogeneic stem cell transplant.[103] Daratumumab is currently under investigation in combination with chemotherapy in

TABLE 68.11 Immunotherapies in Relapsed/Refractory Acute Lymphoblastic Leukemia

Trial	Cell Surface Antigen Target and Agent	Class	Disease Status	*N*	CR (%)	MRD Negativity[a] (%)	Survival Outcomes
	CD19						
Kantarjian[93]	Blinatumomab	BITE	RR	271	119 (44%)	90 (33)	Median OS 7.7 months
Maude[96]	Tisagenlecleucel	CAR-T cell	Pediatric RR	75	61 (81)	61 (81)	OS 76% at 12 months
Shah[97]	Brexucabtagene autoleucel	CAR-T cell	RR	71	39(71)	38(97%)	Median OS 18.2 months
	CD22						
Kantarjian[95]	Inotuzumab ozogamicin	Antibody-drug conjugate	adult RR	49	28 (57)		Median OS 7.9 months

[a] MRD in ALL refers to the presence of leukemic cells less than the threshold of detection by conventional morphologic methods. Patients who achieved a CR by morphologic assessment alone can potentially harbor a large number of leukemic cells in the bone marrow. Current multicolor flow cytometry or PCR methods can detect leukemic cells at a sensitivity threshold of $<1 \times 10^{-4}$ ($<0.01\%$) bone marrow mononuclear cells.

ALL, Acute lymphoblastic leukemia; *BITE*, bispecific T-cell engager; *CAR-T cell*, chimeric antigen receptor–T cell; *CR*, complete remission; *DOR*, duration of response; *EFS*, event-free survival; *MRD*, minimal residual disease; *OS*, overall survival; *PCR*, polymerase chain reaction; *RFS*, relapse-free survival; *RR*, relapsed/refractory ALL; *SCT*, stem cell transplantation.

RR ALL patients 30 years old or younger and may be an exciting agent for treatment of MRD states.

BH3 Mimetics

Venetoclax is a selective BH3 mimetic inhibitor of BCL2, an antiapoptotic protein conferring enhanced survival in leukemia cells, including chronic lymphocytic leukemia, AML, and ALL. Venetoclax is safe and effective in the treatment of CLL and AML as both monotherapy and combined with other agents. Preclinical studies have shown that venetoclax is also active against ALL cells, which are dependent on BCL2 and other antiapoptosis family members, including BCL-XL, for survival. Venetoclax demonstrated synergy with chemotherapy in ALL cell lines and appears to be safe and effective in early phase clinical trials.[104] Preliminary data from an ongoing trial demonstrates high efficacy in the frontline setting with 9/10 patients (90%) achieving CR, but for RR patients the response was limited to 3/8 patients (37.5%).[105] Based on these safety and efficacy data, phase II studies are underway.

In addition to BCL2, preclinical studies have shown BCL-XL may be an important target, particularly for precursor T-ALL. In a recent phase I trial, venetoclax was combined with the BCL-XL inhibitor navitoclax in children and adults with RR B- and T-ALL. Patients could receive chemotherapy at investigator discretion, consisting of PEG-asparaginase, vincristine, and dexamethasone. The most common adverse events were febrile neutropenia and neutropenia. Best response of CR/CRi/CRp was achieved by 25 (54%) patients, with 15 (33%) achieving MRD negativity. Median OS was 9.7 months for B-ALL patients and 6.6 months for T-ALL patients. Eleven (24%) patients went on to allogeneic stem cell transplant or CAR-T cells.[106] These agents are now being considered for combination therapy in frontline T-ALL trials.

Kinase Inhibitors for ALL

Asciminib (ABL001) is a potent, specific, orally bioavailable BCR-ABL1 inhibitor that was approved in 2021 for treatment of TKI-resistant chronic myeloid leukemia (CML) (see Chapter 69) including those with the T315I mutation, which as previously mentioned, is a common mechanism of treatment resistance in patients with Ph $^+$ ALL. Although studies using this agent have focused on CML,[107] there are early-phase data supporting the use of asciminib for patients with advanced T315I-mutant Ph$^+$ ALL and a phase I trial of asciminib with dasatinib and prednisone in newly diagnosed Ph$^+$ ALL unfit for intensive therapy or with relapsed disease has been initiated.

Other TKIs are being explored for patients with Ph-like ALL. Multiple anecdotal reports (reviewed in reference 108) demonstrate efficacy of dasatinib for Ph-like ALL with ABL class fusions. While targeting CRLF2/JAK activation in PH-like ALL has been a greater challenge, an ongoing COG study suggests feasibility and several ongoing studies are evaluating both dasatinib or ruxolitinib added to frontline therapy for patients with Ph-like ALL.[109]

Targeting Intracellular Signaling Pathways

The *NOTCH1* gene encodes a transmembrane receptor protein that drives stem cell commitment to T-cell differentiation. *NOTCH1* activation occurs in more than 50% of patients with precursor T-cell ALL and has been used as a therapeutic target. γ-Secretase is required for *NOTCH1* proteolytic activation. The γ-secretase inhibitor MK-052 caused significant GI toxicity and failed to induce responses in RR T-ALL. To date, due to the off-target effects of γ -secretase inhibition,[110] particularly on the GI tract, the impact of γ-secretase inhibition in T-ALL has been limited and no recent trials have been initiated.

The PI3K/AKT/mTOR pathway is also thought to be active in Ph$^+$ and Ph$^-$ B-ALL. As a single agent, the rapalog sirolimus resulted in only stable disease in RR pediatric ALL. Temsirolimus, everolimus, and sirolimus are each under investigation in combination with chemotherapy in RR ALL. BEZ-235 is a dual inhibitor of PI3K and mTORC1/mTORC2, which in vitro, caused cell cycle arrest and apoptosis in T- and B-ALL, including Ph$^+$ cells, and acted synergistically with chemotherapy.[111] In a phase I trial of BEZ-235 in RR acute leukemia, one out of 10 ALL patients achieved a CR and two additional patients had improvement in blood counts. Similar to rapalogs, this agent may be more effective in combination with chemotherapy.

Epigenetic Modulation

MLL gene rearrangements at position 11q23 occur in approximately 10% of ALL, AML, or MLL and are associated with an aggressive disease course. MLL gene mutations result in oncogenic fusion proteins that associate with disruption of telomeric silencing 1-like (DOT1L), leading to hypermethylation and activation of MLL target genes that drive leukemogenesis. The DOT1L inhibitor EPZ5676 was evaluated in a phase I trial in RR acute leukemias with modest impact.[112] Another exciting approach to targeting *MLL(KMT2A)* fusions, is under active investigation. MLL fusion proteins bind to menin, and this interaction causes leukemia by inducing an aberrant stem cell gene expression program mediated by the homeobox (HOX) genes. Compounds that disrupt binding of KMT2A to menin have shown to have promising antileukemic activity by inhibiting aberrant gene expression programs that result downstream of the MLL fusion. Ongoing early-phase clinical trials demonstrate tolerability and efficacy of this exciting new therapeutic approach to these highly resistant leukemias.[113]

SURVIVORSHIP

Although specific data on long-term complications of young adult survivors of ALL is lacking, the long-term complications of successful treatment of children with ALL have been well described and include neurocognitive and neurologic dysfunction, endocrine and metabolic abnormalities (including obesity), bone toxicity (osteonecrosis), cardiac toxicity, and secondary malignancies. To guide the frequency and focus of medical visits and the ordering of appropriate surveillance tests, comprehensive guidelines have been published in many countries, including North America, where guidelines created by the COG, titled “Long-Term Follow-up Guidelines for Survivors of Childhood, Adolescent and Young Adult Cancers” are available at http://www.survivorshipguidelines.org and should be adopted by the oncology community treating such patients.

FUTURE DIRECTIONS

ALL is a heterogeneous group of diseases with varied clinical outcomes, depending on molecular, cytogenetic, and clinical characterization. Historically, all ALL subtypes behave aggressively and were associated with poor survival outcomes, particularly in adults. The use of intensive pediatric regimens for younger adults with ALL has become standard of care and has resulted in survival rates approaching 70% to 75%. For patients with Ph$^+$ ALL, survival rates have also improved with implementation of next-generation TKIs and reduction in the proportion of patients requiring allogeneic transplant for prolonged survival. In the past several years, immunotherapies such as blinatumomab, inotuzumab ozogamicin, and CAR-T cells remarkably increased our abilities to treat RR ALL and allow more patients to received potentially curative transplants—future generations of these agents/studies may allow for long-term survival without the need for transplant. To that end, studies are now investigating the use of immunotherapies earlier in treatment, including frontline, to improve the depth of response and survival. This may be most relevant for older adults with this disease, where less-intensive combination therapies are already demonstrating significant benefits with less toxicity and improved survival, and it is possible that "chemotherapy"-free regimens will prove to be highly effective for patients with ALL. We have also made significant advances in our understanding of the molecular pathogenesis of this disease, which are translating into effective new targeted therapies as described in the novel agents section. Given the rarity of this disease, it is strongly recommended that patients are referred to centers of expertise, and it is crucial that patients be enrolled in clinical trials designed to evaluate subset-specific therapies to improve survival.

CHAPTER 69

CHRONIC MYELOID LEUKEMIA

Michael W. Deininger

INTRODUCTION AND HISTORICAL PERSPECTIVE

Chronic myeloid leukemia (CML), a rare condition, has had a profound impact on the development of hematology/oncology and modern medicine as a whole (Fig. 69.1A and B). The story started in the 1830s with Alfred Francois Donné of Paris, a remarkable innovator who pioneered the use of microscopy in medicine and was the first to describe the different types of blood cells. When asked to examine the blood specimen of a 44-year-old woman suffering from a painless left-abdominal mass, he noticed the excess of white cells and speculated that the patient's blood may contain pus.[1,2] Donné also organized a *Cours de Microscopie*, which was attended by Edinburgh pathologist John Hughes Bennet who in 1845 published a "Case of Hypertrophy of the Spleen and Liver in which Death Took Place from Suppuration of the Blood."[3] Only a few weeks later Rudolf Virchow of Berlin reported on a very similar patient in an article titled "Weisses Blut" (white blood).[4] Although we do not know for sure that these patients indeed suffered from CML, they highlight CML's most salient features: leukocytosis and splenomegaly. There was disagreement about the cause of the new disease. While Bennett believed it was an infection, Virchow recognized its neoplastic nature and coined the term "leukemia," from the Greek words "λενκον αιμα" meaning "white blood." The ensuing academic dispute was settled cordially: Virchow acknowledged Bennett's priority of discovery and Bennett that leukemia was a cancer of the blood. Perhaps it was the ability of these pioneers to put collaboration first and ego second that turned leukemia research into an engine of medical progress. Initial steps however were tedious. In 1872 Ernst Neumann established the bone marrow as the origin of leukemia and of blood cells in general, but then not much progress was made for almost a century.[5] In 1951 William Dameshek, a visionary with a rare ability of seeing an organizing concept in the unstructured, posited that CML belonged to a larger group of related disorders characterized by overproduction of blood cells in the bone marrow. He called these disorders myeloproliferative disorders (MPDs), a name that stuck.[6]

Just as better microscopes had enabled the first description of leukemia, improvements in chromosome banding led to a breakthrough by cytogeneticists Peter Nowell and David Hungerford from the city of Philadelphia. In 1960 they described an abnormally small G-group chromosome in metaphase spreads from several patients with CML.[7] Ironically, in a now mostly forgotten manuscript, a team from Edinburgh led by Ishbel Tough reported similar findings just a few months later.[8] The discovery of a consistent karyotypic abnormality associated with a cancer settled the debate as to whether DNA or proteins were responsible for transmitting the neoplastic phenotype to the next generation of cells. Anticipating that this was just the first in a long list of cancer chromosomes, the scientists called the new chromosome Philadelphia^1 (Ph^1, now usually referred to as Ph) after the place of its discovery. One lesion in all CML cells suggested that the leukemia traced its origins back to a single ancestral cell. Formal proof for this idea was provided by Philip Fialkow who showed that the neutrophils from a female CML patient expressed only one isoform of the X chromosomal gene glucose-6-phosphate dehydrogenase (G6PD). This was consistent with inactivation of either a maternal or paternal X chromosome in all cells rather than the random inactivation characteristic of polyclonal tissues.[9]

In 1973, Janet Rowley recognized that Ph was the product of a t(9;22)(q34;q11.1) reciprocal translocation rather than only a shortened chromosome 22.[10] Over the following 25 years, the genetic anatomy and biochemical consequences of t(9;22)(q34;q11.1) were revealed with increasing resolution. Groups led by Eli Cannani, John Groffen/Nora Heisterkamp, and Owen Witte contributed to the identification of the genes juxtaposed by t(9;22).[11–13] The chromosome 9 fusion partner was found to be *ABL1* (formerly *ABL*), the human homolog of v-abl, the oncogene of the Abelson murine leukemia virus (A-MuLV).[14,15] On the derivative chromosome 22, *ABL1* sequences consistently translocated to a genetic region that became known as the "breakpoint cluster region" (*BCR*), a name that was subsequently used for the new gene fused upstream of *ABL1*. The next critical step was the discovery that BCR-ABL1, similar to v-Abl, was a constitutively active tyrosine kinase and that kinase activity was required for cellular transformation.[16] Lastly, mice transplanted with bone marrow engineered to express BCR-ABL1 were shown to develop an MPD resembling CML, another milestone in the history of cancer research.[17]

CML therapy developed slowly. Arsenicals, in use for cancer treatment since ancient times, were the only treatment available in the 19th century, usually in the form of Fowler's solution, which contained potassium arsenite. The German physician Heinrich Lissauer is credited with the first publication on the remarkable efficacy of Fowler's solution in a patient with leukemia.[18] We may suspect that the reviewers of his paper gave him a pass on novelty, since the use of arsenic for cancer therapy had been described by the poet Valmiki in the Indian Ramayana in approximately 500 BC. As a curiosity, in an 1882 *Lancet* paper, Conan Doyle, better known for his Sherlock Holmes detective stories, published on a patient with the clinical presentation of CML who achieved a partial response to arsenic.[19] In the 1920s, radiotherapy was introduced for symptomatic relief of tender splenomegaly, and remained the mainstay of CML therapy for the first half of the 20th century. Busulfan (1959), an alkylating agent discovered at the Chester Beatty Laboratories in London, was the first drug that reliably controlled white blood cell counts in CML and has retained a place in conditioning regimens for allogeneic hematopoietic cell transplantation (HCT). Ten years later, hydroxyurea was introduced as the first intervention that prolonged survival, although by only a small margin.[20,21] A breakthrough was achieved in the late 1970s when the Seattle group reported the disappearance of Ph in CML patients who underwent HCT, the first cures of CML.[22] Soon after that, interferon-α (IFNα) was found to induce durable complete cytogenetic responses (CCyRs) and long-term survival in 10% to 20% of patients.[23] In 1992, Alexander Levitzki proposed the use of ABL inhibitors to treat leukemias driven by ABL oncogenes, but unfortunately, none of his so-called tyrphostins were developed for clinical use.[24] At about the same time, scientists at Ciba-Geigy had synthesized a potent inhibitor of ABL1 termed GCP57148B that is now known as imatinib.[25,26] Of note, GCP57148B's anti-ABL activity was the serendipitous byproduct of a drug development effort to identify inhibitors of platelet-derived growth factor receptor (PDGFR) for cardiovascular indications. Clinical trials initiated by Brian Druker, against the skepticism of the manufacturer, rapidly established the compound's activity in patients with CML and revolutionized CML therapy.[26–28] Solving the crystal structure of ABL1 in complex with imatinib provided the foundation for subsequent studies into the auto-regulation of ABL1 kinase activity and its disruption in BCR-ABL1.[29–31] These studies were of fundamental importance for our understanding of kinases and their regulation in physiological

Figure 69.1 THE HISTORY OF CHRONIC MYELOID LEUKEMIA. (A) Timeline of important developments in leukemia/CML. (B) Major contributors to CML biology and treatment. From left upper to right lower corner: Alfred Donné, Hughes Bennet, Rudolf Virchov, Ernst Neumann, William Dameshek, Peter Nowell and David Hungerford, Phillip Fialkow, Janet Rowley, Nora Heisterkamp, Owen Witte, Eli Canaani, Alexander Levitzki, Alois Matter, Nick Lydon, Brian Druker. Note that many others have made significant and lasting contributions, but for the sake of space could not be included here. *CML*, Chronic myeloid leukemia.

and aberrant signal transduction. Despite imatinib's general efficacy, subsets of patients developed resistance, frequently due to point mutations in BCR-ABL1, stimulating the development of subsequent generations of tyrosine kinase inhibitors (TKIs).[32–34] The latest development is asciminib, an allosteric ABL inhibitor that mimics the physiological autoinhibition of ABL1.[35,36]

There is compelling evidence that the most primitive CML cells are not dependent on BCR-ABL1 kinase activity,[37,38] explaining why residual leukemia remains detectable in many CML patients treated with TKIs. Surprisingly a plethora of studies has demonstrated that 40% to 60% of patients with deep molecular responses (DMRs) maintain remission after discontinuation of TKIs, a state termed treatment-free remission (TFR).[39] While survival remains the universal goal for all CML patients, TFR has gained traction as a new target for selected patient populations, particularly young individuals.[40]

The unprecedented success of TKIs to treat CML established a paradigm for molecularly targeted therapy that informs approaches in other types of cancer. However, many scientific, clinical, and societal questions remain. CML mortality is not zero, and the prognosis for patients who progress to blast phase CML (BP-CML) remains very poor. Despite improved understanding of blastic transformation at the molecular level, no fundamentally new treatments have emerged beyond chemotherapy followed by HCT. At the other extreme, increasing the pool of TRF eligible patients and improving the success rate will be crucial to minimize long-term TKI toxicity. However, as the biological underpinnings of TFR have remained largely elusive, rational approaches to improve over the current situation are lacking. Last but not least, the exorbitant costs of TKIs, particularly in the United Stated, raise ethical and societal questions that cannot be answered on medical grounds alone.[41] Again, CML has prepared the ground for fundamental discussions far beyond what one might expect from an orphan disease.

EPIDEMIOLOGY

CML occurs with an annual incidence of 1.0 to 1.5 per 100,000, without significant racial or geographic differences, but a slight male predominance of approximately 1.5. The median age at CML diagnosis is above 60 years in the developed world, but lower in developing countries, reflecting differences in access to medical care or—much less likely—disease biology. CML is generally rare in children, but cases have been reported even in infants. Familial occurrence has been observed, but there is no evidence for a general familial predisposition. The only well-documented risk factor is ionizing radiation. In the survivors of the atomic bombings in Japan, CML incidence increased, peaking 8 to 10 years post exposure.[42] Elevated rates of CML were also seen in patients treated with radiotherapy for ankylosing spondylitis and those exposed to thorotrast, an alpha-emitting contrast medium widely used in the 1930s and 1940s.[43,44] In contrast, there is no association between benzene exposure and CML.[45] As a result of the vastly improved survival afforded by TKIs, CML prevalence in the United States is predicted to rise from 70,000 in 2010 to 180,000 in 2050.[46] At that point CML will become the most prevalent myeloid neoplasm, with considerable implications for health care costs.

MOLECULAR BIOLOGY

BCR-ABL1 Translocation and Fusion Gene (Chapter 57)

Ph is the result of a reciprocal translocation between the long arms of chromosomes 9 and 22 [t(9;22)(q34;q11.2)] that fuses sequences from the *ABL1* gene on 9q34 downstream of the *BCR* gene on 22q11 (Fig. 69.2A). The chromosome 22 breaks localize almost exclusively to one of three *BCRs* and determine which parts of *BCR* are retained in the *BCR-ABL1* fusion mRNA and protein. In contrast, the chromosome 9 breaks can occur over a large genetic region, 5′ of *ABL1* exon Ib, 3′ of *ABL1* exon Ia, or most commonly between the two alternative first *ABL1* exons (Fig. 69.3B). Despite the different breakpoints, splicing almost invariably leads to fusion mRNAs that encompass *ABL1* exons 2 to 11.[47] Breakpoints in the minor *BCR* (m-*BCR)* generate an e1a2 fusion mRNA and p190$^{BCR-ABL1}$, which is found in two-thirds of Ph$^+$ acute lymphoblastic leukemia (ALL) cases, but very rarely in CML, where it is associated with monocytosis and an aggressive clinical course.[48,49] The origin and biology of p190$^{BCR-ABL1}$-positive CML is mysterious. Either m-*BCR* rearrangements are much less likely to occur in hematopoietic stem cells (HSCs) than the major *BCR* (M-BCR) rearrangements typical of CML, or the cell of origin is different, or an as yet unknown concomitant somatic mutation creates a state conducive to transformation by p190$^{BCR-ABL1}$. In the vast majority of CML patients, the break localizes to the M-*BCR*, generating e13a2 or e14a2 (formerly referred to as b2a2 and b3a2) fusion mRNAs and a p210$^{BCR-ABL1}$ fusion protein. p230$^{BCR-ABL1}$, the largest of the fusion proteins, is derived from a break in the micro *BCR* (μ-*BCR*) that generates e19a2 mRNA. p230$^{BCR-ABL1}$ is associated with neutrophilic predominance and a more benign disease.[50] There are a number of rare *BCR-ABL1* variants, some of which may be associated with a more aggressive clinical course.[51] Additionally variants can give rise to misleading reverse transcription polymerase chain reaction (RT-PCR) results and cannot be followed using standard quantitative PCR (qPCR) assays.[51–53] Approximately two-thirds of CML cases also express the reciprocal *ABL1-BCR* mRNA, but there is no definitive evidence that this influences disease biology or prognosis.[54,55] However, absence of *ABL1-BCR* mRNA is an indirect indication for deletions flanking the breakpoints in *BCR*, *ABL1*, or both. For unknown reasons, these deletions are associated with significantly reduced survival in patients treated with IFN-α, but their adverse impact is reduced or abolished by TKI therapy.[56,57]

BCR and ABL1 Proteins and Their Contribution to Cellular Transformation

BCR is a ubiquitously expressed 160kD cytoplasmic protein encompassing several functional domains, including an N-terminal coiled-coil motif, followed by a serine/threonine kinase motif whose only known substrate is the 14-3-3 family protein Bap-1,[58] a *dbl*-like (DH) domain and a pleckstrin-homology (PH) domain (see Fig. 69.3A). DH had been thought to stimulate exchange of guanidine triphosphate (GTP) for guanidine diphosphate (GDP) on Rho guanidine exchange factors,[59] but recent structural and biochemical studies failed to confirm this.[60,61] The PH domain binds to various phosphatidylinositol (PI)-phosphates, impacts subcellular protein localization, and is required for interactions with selected proteins.[60,61] The BCR C-terminus contains a putative calcium-dependent lipid binding (CaLB) site and a GTPase activating function (RAC-GAP). The latter constrains activity of Ras-related C3 botulinum toxin substrate (RAC), a small GTPase that regulates actin polymerization and an nicotinamide adenine dinucleotide phosphate hydrogen (NADPH) oxidase in phagocytic cells.[62,63] *Bcr*$^{-/-}$ mice are viable and fertile, the only known defect being an increased oxidative burst in neutrophils.[64] BCR can be phosphorylated on several tyrosine residues, most importantly tyrosine 177, which binds growth factor receptor bound protein 2 (GRB2), an adapter molecule involved in rat sarcoma virus (RAS) activation in CML cells.[65–67] The question why p190$^{BCR-ABL1}$ and p210$^{BCR-ABL1}$ are associated with ALL and CML, respectively, has long been a matter of debate.[59,68,69] Recent work has shown that the protein networks entertained by p190$^{BCR-ABL1}$ and p210$^{BCR-ABL1}$ are profoundly different, and the differences have been attributed to the retention of the PH domain in p210$^{BCR-ABL1}$.[60] It remains unclear how this impacts lineage commitment and why HSCs are susceptible to transformation by p210$^{BCR-ABL}$, while p190$^{BCR-ABL1}$ targets pre-B cells.[70]

ABL1 is the human homologue of the v-*abl* oncogene of the A-MuLV.[71] The 145-kDa ABL1 protein is ubiquitously expressed and encodes a non-receptor tyrosine kinase.[72] Two isoforms arise from alternative splicing of the first exon. ABL1a lacks the first 19 amino acids, which are retained in ABL1b and include a glycine in position 2 that can be myristoylated.[73] The N-terminal region contains three SRC homology domains (SH1 to SH3). SH1 carries the tyrosine kinase function, while the SH2 and SH3 domains engage in protein-protein interactions and participate in regulation of kinase activity (see Fig. 69.3B).[74] The center of ABL1 features proline rich sequences that interact with SH3 domains of other proteins such as Crk.[75,76] The C-terminus contains nuclear localization, DNA binding,[77] and actin-binding motifs.[78] Several functions have been attributed to ABL1, including inhibition of cell cycle progression and proliferation,[79,80] integrin signaling,[81] and DNA repair.[82–86] Mice with germline deletion of *Abl1* exhibit high perinatal mortality, runting, and skeletal and immune system defects.[87,88] ABL1 kinase activity is tightly controlled in physiological conditions through allosteric mechanisms that involve a myristate-binding pocket at the base of the SH1 domain. Mice null for *Abl1* and the *Abl*-related gene (formerly

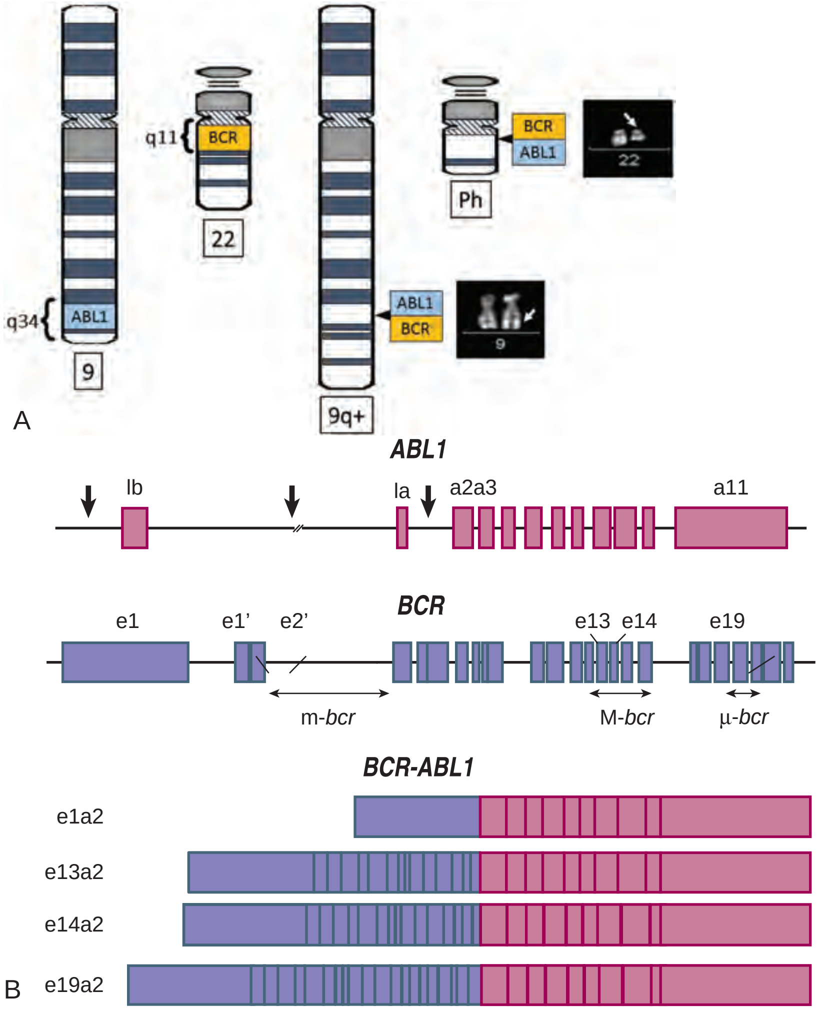

Figure 69.2 GENETIC ANATOMY OF THE *BCR-ABL1* TRANSLOCATION. (B) *(upper panels)* Genomic loci of *ABL1* and *BCR* with exon numbering. The three breakpoint cluster regions in *BCR* are also indicated. *(lower panel)* Fusion mRNAs derived from the chimeric genes. Note that the e13a2 and e14a2 fusion mRNAs were previously referred to as b2a2 and b3a2, respectively. *BCR*, Breakpoint cluster region

Arg, now *Abl2*) are embryonically lethal due to absence of neurulation.[89] Gain of function in the germline is also detrimental, as shown by a recent report of mutations in the myristate binding pocket that confer constitutive kinase activation and are associated with cardiac and skeletal defects.[90] The emerging complex picture suggests that ABL1 may be best characterized as a cellular module that integrates extra- and intracellular signals to influence decisions with regard to cell cycle and apoptosis. The latter observation raised considerable concerns about the potential side effects of clinical ABL inhibitors that fortunately were not confirmed.

Constitutive Kinase Activation in the BCR-ABL1 Fusion Protein

In contrast to ABL1, BCR-ABL1 is constitutively active and excluded from the nucleus. Revealing the mechanism by which replacing the ABL1 N-terminus with BCR sequences leads to kinase activation has led to deep insights into the regulation of ABL1.[91] The coiled-coil domain of BCR (see Fig. 69.3A) promotes dimerization, which allows for an initial transphosphorylation event, followed by autophosphorylation of additional tyrosine residues that fully activate the kinase.[92] Other proteins with the ability to form dimers can substitute for BCR, such as ETV6 and NUP214 that form ABL1 fusion genes associated with a myeloproliferative neoplasm (MPN) or ALL.[93,94] The N-terminal “cap” region of ABL1, when myristoylated, binds to a hydrophobic pocket at the base of the kinase domain, resulting in a conformation that resembles a latch that holds the kinase in an inactive state.[30,31,95] However, small molecules binding to the myristate pocket inhibit kinase activity, indicating that the concept of a “mechanical” latch is too simplistic. Rather than that, an allosteric mechanism controls kinase activity that does not require the ABL1 N-terminal sequences and hence is preserved and amenable to therapeutic targeting in BCR-ABL1.[35,96] How precisely information is communicated from the myristate pocket to the catalytic site is unknown. Recent data suggest that reverse signaling is also possible, as mutations in the ATP site can influence binding of small molecules to the myristate pocket.[97] Additional levels of regulation exist: certain residues within the SH2 domain participate in the regulation of kinase activity,[98] and trans-acting binding partners such as the ABL1 interacting proteins have been implicated as physiological inhibitors.[99,100]

Several domains or amino acid residues in BCR-ABL1 are critical for cellular transformation. In the ABL1 portion they include the kinase domain, SH2, and actin-binding domains (see Fig. 69.3C).[101] Additionally the SH3 domain contributes to aberrant regulation of homing, adhesion, and migration.[102] Transformation-relevant domains in the BCR portion include a coiled–coil motif contained in amino acids 1 to 63, the tyrosine at position 177, and phosphoserine–threonine-rich sequences between amino acids 192 to 242 and 298 to 413.[103] Whether or not a particular feature is essential may depend on the cellular context. For example, SH2 deletion mutants of BCR-ABL1 are defective for fibroblast transformation, but they retain the capacity to transform cell lines to factor independence and are leukemogenic in mice.[103]

Figure 69.3 STRUCTURAL DOMAINS AND SIGNALING MOTIFS IN BCR, ABL1, AND BCR-ABL1 PROTEINS. (A) BCR protein. Shown are the N-terminal coiled coil (oligomerization), serine/threonine kinase, Dbl-like domain (DH), pleckstrin homology (PH) domain, calcium binding domain (CalB), and Rac-GAP domain. (B) ABL1 protein. Shown are SRC homology domains 1–3 (SH1–3), proline-rich motifs (P), nuclear localization signals (NLS), DNA binding domain, and actin binding domain. (C) p210BCR-ABL1 and p190BCR-ABL1 proteins. Note that p210BCR-ABL1 retains the DH and PH domains, which are missing from p190BCR-ABL1. *BCR*, Breakpoint cluster region.

Aberrant Signaling in BCR-ABL1 Transformed Cells

BCR-ABL1 signaling is one of the most intensely studied areas in biomedical research. Three decades of research have identified numerous BCR-ABL1 substrates, binding partners, and downstream signaling molecules involved in cellular transformation, and the number is still growing (Fig. 69.4). Efforts have been directed at linking these pathways to specific characteristics of CML cells, such as increased proliferation, reduced apoptosis, abnormal adhesion and migration, or genetic instability. The accumulated data are overwhelming, and a comprehensive review of the multiple pathways implicated in BCR-ABL1 transformation is beyond the scope of this chapter. As a note of caution, despite evidence from CML cell lines and primary CML cells, mouse models using homozygous deletions of signaling proteins have identified very few pathway components with a truly essential role for BCR-ABL1–induced leukemia. This speaks to the extensive redundancy of the BCR-ABL1 transformation network and/or to the limitations of the disease models.

Phosphatidylinositol-3 Kinase

BCR-ABL1 activates phosphatidylinositol-3 kinase (PI3K) through at least two separate mechanisms. The first is initiated by autophosphorylation of BCR-ABL1 tyrosine 177 (Y177), which generates a docking site for the GRB2 adapter protein. GRB2 recruits GAB2, another adapter, into a complex that activates PI3K.[104,105] Alternatively, PI3K can be activated by complex formation between the PI3K p85 regulatory subunit, and the BCR-ABL1 substrates casistas B-lineage lymphoma (CBL) and CRK like (CRKL), which bind to the SH2 and proline-rich domains of BCR-ABL1.[106] The main downstream target of PI3K is the serine-threonine kinase AKT, a major conduit for oncogenic signals in many types of cancer. In BCR-ABL1$^+$ cells, AKT enhances survival by phosphorylating forkhead O transcription factor 3a (FOXO3a) and pro-apoptotic proteins like BCL2 associated agonist of cell death (BAD).[107–109] Phosphorylated FOXO3 is excluded from the nucleus, leading to downregulation of important transcriptional targets such as p27. Phosphorylated BAD is no longer able to neutralize anti-apoptotic BCL2 family members such as BCL2 and BCLX$_L$, promoting survival. Furthermore, AKT activates mammalian target of rapamycin (mTOR), which phosphorylates ribosomal proteins p70S6 kinase (S6K) and 4E-BP1. S6K, a serine/threonine kinase, phosphorylates multiple substrates that collectively promote cell proliferation. Phosphorylated mTOR has been shown to inactivate 4EBP-1, releasing the translation initiation factor eIF4E from inhibition to enhance protein synthesis.[110,111] In addition to activating AKT, PI3K promotes proteasomal degradation of p27 through upregulation of SKP2, the F-Box recognition protein of the SCF^{SKP2} E3 ubiquitin ligase. Accordingly, absence of SKP2 from leukemia cells prolongs survival in a murine CML model.[112]

Figure 69.4 GROSSLY SIMPLIFIED REPRESENTATION OF SIGNALING PATHWAYS ACTIVATED IN CML CELLS. Autophosphorylation generates docking sites on BCR-ABL1 that promote binding of intermediary proteins, some of which are also BCR-ABL1 substrates such as CRKL and CBL, forming a multimeric complex. The BCR-ABL1 signaling complex activates multiple downstream pathways that inhibit apoptosis, enhance proliferation, perturb adhesion and migration, and impart genomic instability. Only few of these downstream mediators are essential to BCR-ABL's ability to transform cells, indicating that the signaling network is highly redundant. For details see text. *BCR*, Breakpoint cluster region.

RAS/Mitogen-Activated Protein Kinase Pathways

A long-known pathway of RAS activation is phosphorylation of tyrosine 177 with recruitment of GRB2 and Son of Sevenless (SOS) into a complex that promotes exchange of GTP for GDP on RAS.[104,113] GTP-bound RAS activates the serine-threonine kinase RAF-1,[114,115] which in turn activates mitogen-activated protein kinase (MAPK). Recently, a genetic screen identified inactivation of LZTR1 as a promoter of RAS activation in TKI-treated CML cells.[116] Mechanistically LZTR1 controls KRAS expression by enhancing interaction with the CUL3 E3 ligase, promoting proteasomal degradation. Other small GTPases like RAC1/2 have also been implicated in BCR-ABL1 signaling[117] and genetic absence of RAC1/2 has been shown to attenuate *BCR-ABL1* leukemia in a murine model.[118]

Janus Kinase (JAK)/Signal Transducer and Activator of Transcription (STAT) Pathway

The STAT5 transcription factor is constitutively tyrosine-phosphorylated in CML cells. Initial experiments in mice failed to demonstrate a critical role for STAT5.[119] However, it was subsequently discovered that the presumed *Stat5* knockout mice used in this study were not null for *Stat5*, but expressed a partially functional N-terminally deleted protein. While STAT5 is not required for the initiation of CML, there is convincing evidence that it plays a rate-limiting role in leukemogenesis.[120,121] Absence of only STAT5A or overexpression of a dominant-negative STAT5 mutant in BCR-ABL1 expressing bone marrow cells attenuates CML.[122] Conditional deletion of STAT5 prevents the establishment of active CML in mice, but does not eliminate the BCR-ABL1 expressing cells.[120] The consequence of constitutive STAT5 activation is inhibition of apoptosis by enhancing transcription of anti-apoptotic proteins like MCL-1 and BCL-X_L.[123] BCR-ABL1 may activate STAT5 through direct phosphorylation or indirectly by promoting phosphorylation by HCK or JAK2.[124,125] The role of JAK2 itself is controversial. Previous studies had suggested that JAK2 plays an important if not essential role,[126] while a recent report using conditional knockout technology showed that murine CML does not require JAK2.[127] In contrast, JAK2 may have an important role in promoting survival of CML stem cells (from here onward referred to as LSCs).[128,129]

Cytoskeletal Proteins

Several BCR-ABL1 substrates are involved in adhesion and migration, including focal adhesion kinase (FAK), CRKL, paxillin, p130CAS, and HEF1.[130–135] It is thought that this aberrant phosphorylation is responsible for the defect in integrin-mediated adhesion of CML progenitors to bone marrow stroma and extracellular matrix. Alternatively, integrin function may be compromised through RAS activation or BCR-ABL1 binding to F-actin.[104,136] Lastly one report found that a kinase inactive BCR-ABL1 variant causes an adhesion defect, consistent with a process that is independent of BCR-ABL kinase activity.[137] Given that adhesion of integrins inhibits proliferation of hematopoietic progenitors, the defect in integrin function may contribute to the premature circulation as well as the abnormal proliferation of Ph^+ progenitor cells.[137]

DNA Damage Surveillance and Repair Pathways

Without effective therapy, chronic phase of CML (CP-CML) invariably progresses to BP-CML, testimony to the profound genetic instability of CML cells. CML $CD34^+$ cells contain more reactive oxygen species (ROS) compared to normal controls, and this is particularly pronounced in CML-BP cells.[138–140] ROS cause DNA damage by generating oxidized bases and double-strand breaks (DSB), which are up to eightfold more frequent in CML than in normal cells.[141] While ROS generation in CML cell lines and progenitor cells is controlled by BCR-ABL1 through activation of PI3K, studies in mice have shown that LSCs continue to accumulate ROS-induced DNA damage despite TKI inhibition of BCR-ABL1.[142,143] This suggests that genetic evolution may continue in patients on TKIs as long as they harbor residual leukemia. Fortunately, this concern was not borne out in the clinic, at least in patients with a CCyR or major molecular response (MMR), whose progression rate is low. Additional mutagenic mechanisms operational in lymphoid blast phase cells are activation of activation-induced cytidine deaminase (AID), which promotes point mutations, and RAG-mediated recombination, which promotes structural recombination events.[144,145] The consequences of increased DNA damage are aggravated by the impairment of DNA damage surveillance and repair. Multiple mechanisms have been implicated, including BCR-ABL1 kinase-independent mechanisms. For instance, BCR-ABL1 impairs the intra-S-phase cell cycle checkpoint through suppression of checkpoint kinase 1 (CHK1), either by inhibiting the nuclear protein kinase ATR[146] or by downregulating BRCA1, a substrate of ataxia telangiectasia mutated (ATM).[147] There is also aberrant regulation of DSB repair pathways. In addition to BRCA1, the catalytic subunit of DNA-dependent protein kinase (DNA-PKcs) is downregulated in $CD34^+$ CML progenitors, leading to error-prone non-homologous end-joining (NHEJ), rather than more faithful D-NHEJ,[148] thereby enhancing the effects of BCR-ABL1–induced ROS. While these deficiencies result in genomic instability and increase the risk of progression, they also offer therapeutic opportunities. Cycling cells have access to a range of DNA repair mechanisms, including homologous recombination (HR), single strand annealing (SSA), transcription-associated homologous recombination (TA-HR), and NHEJ. In contrast, quiescent cells have limited options, using mostly NHEJ (Fig. 69.5A). There are differences in the usage of the various DNA repair pathways between LSCs and HSCs that in the future may provide individualized therapeutic opportunities, based on the principle of synthetic lethality. For instance BRCA1/2 is frequently downregulated in CML. Additionally, some cases have downregulated one of the components of D-NHEJ, rendering them vulnerable to a combination of PARP inhibitors such as olaparib and inhibitors of RAD51, while cycling HSCs can resort to BRCA1/2-based HR, and quiescent HSCs to D-NHEJ (see Fig. 69.5B, C).[149,150] There is little evidence that TKIs themselves cause DNA damage, although imatinib was reported to induce centrosome abnormalities in vitro.[151] Conflicting data have been reported regarding the risk of second (non-hematologic) malignancies in CML patients on TKIs but there is consensus that any excess incidence is related to CML rather than TKI therapy.[152,153] Similarly there is no evidence that the clonal cytogenetic abnormalities in Ph-negative cells (CCA/Ph^-) detected in 5% to 10% of CML patients with a cytogenetic response to TKI therapy are induced by TKIs.[154]

A wealth of data on BCR-ABL1 signaling has been amassed, yet a complete picture is still elusive. As conventional approaches have typically focused on single pathways, efforts are now underway to characterize more comprehensively BCR-ABL1 signaling by quantitative genomics.[60,155] These data suggest that cellular processes in CML rely on integrated networks rather than single pathways, which cooperate to fully realize the leukemogenic potential of BCR-ABL1.

CELLULAR BIOLOGY

Cell of Origin

Current thinking holds that *BCR-ABL1* is both necessary and sufficient to produce the CP-CML. Unlike some fusion genes associated with acute myeloid leukemia (AML), such as *MOZ-TIF2*, *BCR-ABL1* does not confer HSC self-renewal, implying that the initial translocation event must occur in a multipotent hematopoietic HSC already endowed with this property.[156] Evidence in support of this comes from mouse models and clinical observations. Mice transplanted with bone marrow cells infected with a *BCR-ABL1* retrovirus develop an oligoclonal CML-like MPN, suggesting that a second event is not required.[13] Similarly mice expressing a doxycycline-repressible BCR-ABL1 allele develop CML upon withdrawal of doxycycline, which regresses upon re-exposure to doxycycline.[25] TKIs restore polyclonal hematopoiesis as assessed by X chromosome inactivation.[154] However the clinical variability of CP-CML, particularly the highly variable time to transformation to AP/BP-CML, indicates the presence of major disease modifying factors. Between 5% and 10% of CP-CML cases have additional clonal cytogenetic abnormalities in Ph^+ cells (CCA/Ph^+) at diagnosis, and this is associated with a more aggressive clinical course.[157] In almost all cases, CCA/Ph^+ disappear upon achievement of a cytogenetic response, suggesting they reflect evolution of the Ph^+ cell clone (Fig. 69.6). Next generation sequencing (NGS) has revealed mutations in epigenetic modifier genes such as *TET2, DNMT3A*, and *ASXL1* in ~30% of CP-CML patients at diagnosis.[158–160] In most but not all cases, these mutations became undetectable at the time of cytogenetic or molecular response, indicating that CML may develop either truly de novo or on the background of clonal hematopoiesis (CH) (see Fig. 69.6). This model is consistent with the observation that CML can occur at any age, while complex myeloid neoplasms such as chronic myelomonocytic leukemia (CMML) almost invariably develop from preceding CH and as such are restricted to older individuals.[161,162] The impression is that patients with additional somatic mutations at diagnosis have a worse prognosis, but this is less well established compared to CCA/Ph^+, and more data is needed.[159,163] That somatic mutations in addition to Ph may happen at any point during the evolution of CML speaks to the remarkable capacity of BCR-ABL1 to drive the CML phenotype, either alone or on a genetically modified background.

Chronic Myeloid Leukemia Hematopoiesis

Unlike in acute leukemia, the hierarchical organization of hematopoiesis is initially maintained in CML, although there is lineage imbalance in favor of the myeloid series and a left-shift of granulopoiesis. Although maturation is delayed, cellular function is mostly normal, evidenced by the fact that CML patients in the chronic phase are not at increased risk of infection or bleeding. *BCR-ABL1* is detected in cells belonging to all hematopoietic lineages, including B cells and T cells.[164] Consistent with the clinical presentation, the thrust of *BCR-ABL1*–induced cellular expansion targets the myeloid progenitor cell compartment, which is almost exclusively Ph^+ (see Fig. 69.6). In contrast, in most newly diagnosed patients the majority of the most primitive cells (defined as long-term culture initiating cells, LTC-ICs, or quiescent $CD34^+$ cells) are partially or even predominantly Ph^-.[165] These normal HSCs are the basis for cytogenetic and molecular

responses to therapy. The cause of the myeloid bias is incompletely understood. One possible explanation is that BCR-ABL1 alone is insufficient to overcome the powerful metabolic growth restraint placed on lymphoid precursor cells, which is thought to minimize the risk of malignant transformation during V(D)J rearrangement or T-cell receptor diversification.[166] As such BCR-ABL1-positive chronic lymphocytic leukemia does not exist. However, when disruption of orderly B-cell (and rarely T-cell) differentiation abrogates the growth restraint, BCR-ABL1-positive ALL ensues. In the B-cell lineage this is accomplished by inactivation of lineage-specific transcription factors such as IKZF1 or PAX5.[166]

Leukemia stem cells (LSCs) and what distinguishes them from HSCs have been the topic of intense research. It is important to remember that the ultimate diagnostic test for stemness is functional—the ability of a cell to generate progeny of all lineages in vivo, while phenotypic markers are surrogates by definition. As such, the terms HSC and LSC frequently denote populations of cells that are enriched for functionally defined "true" stem cells, but not pure populations. For instance, in many studies stem cells are conveniently defined as Lineage$^-$CD34$^+$CD38$^-$, but less than 10% of these cells are functionally stem cells. As of 2020, no universal immunophenotypic marker had been identified that separates LSCs from HSCs, but strategies using multiple markers have achieved considerable enrichment for BCR-ABL$^+$ cells. The issue is complicated by the fact that some but not all markers are regulated by BCR-ABL1 kinase activity, and that TKIs predominantly eliminate proliferating LSCs with a "late" myeloid signature, while relatively sparing the most primitive LSCs.[167] As a consequence, the immunophenotype of LSCs in untreated CML patients is different from that in patients with residual disease on TKIs (Table 69.1). Some clinical features of CML can be linked to biological aberrancies of LSCs. For instance LSCs exhibit reduced integrin-mediated adhesion to bone marrow stroma and abnormal migration to CXCL12 (SDF1), which may account for leukocytosis and extramedullary hematopoiesis in spleen and liver.[168,169] Transcriptomic profiling of CD34$^+$38$^-$ cells showed that quiescent LSCs are primed to proliferate compared to HSCs, explaining their hypersensitivity to cytokines such as IL-3 and G-SCF.[149,170]

TABLE 69.1 **Immunophenotypic Markers of Primitive Chronic Myeloid Leukemia Cells in Chronic Phase at Diagnosis and on Tyrosine Kinase Inhibitor Therapy**

	HSC	LSC (Diagnosis)	LSC (on TKI)
Lineage	–	–	–
CD34	+++	+++	+

HSC, Hematopoietic stem cell; *TKI*, tyrosine kinase inhibitor.
Adapted from Warfvinge R, Geironson L, Sommarin MNE, et al. Single-cell molecular analysis defines therapy response and immunophenotype of stem cell subpopulations in CML. *Blood*. 2017;129(17):2384–2394.

A question of considerable clinical importance is whether CML stem cells are dependent ("addicted") to BCR-ABL1 or not. The fact that residual BCR-ABL1$^+$ cells remain detectable by PCR in most patients on TKIs has been interpreted as evidence for persistence of LSCs despite continued suppression of BCR-ABL1 kinase activity. Consistent with this, primitive CML cells survive TKI treatment ex vivo.[37,38] However, recent data have revealed that long-lived B cells and less frequently T cells account for most of the positive PCR results in patients in TFR, while granulocytes are consistently BCR-ABL1-negative. These data do not prove that multipotent CML stem cells are absent, but they explain the puzzling observation of positive PCR results in patients with stable TFR for years. Conceptually the central question is whether an LSC with kinase-disabled BCR-ABL1 is equal to a normal HSC or is still "rewired." This could happen through at least three mechanisms. First there is compelling data that some BCR-ABL1 functions are kinase-independent.[137,150] Whether these functions alone are sufficient to support long-term survival of LSCs is unknown. Second epigenetic reprogramming as a result of exposure to unopposed BCR-ABL1 kinase activity could persist even when BCR-ABL1 is no longer active.[171] Third the presence of a large multi-domain protein like BCR-ABL1 may interfere with physiological signaling, for instance through sequestration of adaptor proteins. Indeed considerable evidence has accumulated to suggest that LSCs exhibit specific vulnerabilities that may be exploitable therapeutically, either alone or in combination with TKIs (Table 69.2). Although several pathways such as β-catenin, PP2A, and JAK2 are supported by multiple independent studies, translation of these data into hypothesis-driven clinical trials has been excruciatingly slow. As a result, conclusive data regarding clinical efficacy are mostly missing or inconclusive, and thus far no new clinical approaches have emerged that could be considered standard of care.

TRANSFORMATION TO ACCELERATED AND BLAST PHASE

As the CP-CML is compatible with life, one could argue that the main objective in CML therapy is the prevention of transformation to BP-CML, an acute leukemia with myeloid (M-BP) or pre-B-cell phenotype (L-BP). A host of genetic alterations has been associated with transformation to accelerated phase (AP)/BP (Fig. 69.7). CCA/Ph$^+$ is present in 70% to 80% of cases and includes a number of nonrandom abnormalities. Classically, +8, +Ph, i(17q), and +19 were considered as "major route" abnormalities, although this is not a universally accepted definition.[172] Several other recurrent abnormalities are also associated with a poor prognosis, including −7 and 3q26 abnormalities.[157] Many other cytogenetic changes have been described in smaller subsets of patients, and their prognostic impact is less well established. However, the acquisition of any CCA/Ph$^+$ in a patient on TKI therapy is consistent with a diagnosis of AP-CML irrespective of other disease features.[40] NGS has revealed point mutations, indels, and fusion genes in addition to BCR-ABL1 (see Fig. 69.7). For example, inactivating mutations of *RUNX1* occur in ~25% of M-BP cases, respectively, while ~55% of L-BP cases have inactivating mutations in *IKZF1*.[159,173,174]

BCR-ABL1 expression tends to increase with progression to BP. In some patients, rising *BCR-ABL1* mRNA levels are associated with duplication of Ph, but in the majority this seems to result from transcriptional upregulation due to as yet unknown mechanisms.[175] The increase in BCR-ABL1 expression promotes expression of SET, which inhibits the tumor suppressor phosphatase PP2A by forming a complex with the PP2A catalytic subunit (PP2Ac). PP2A activates SHP-1 to de-phosphorylate BCR-ABL1 and other important substrates.[176] Reduced PP2A activity increases BCR-ABL1 activity, further enhancing the signal in a positive feedback loop. Reduced SHP-1 activity has been associated with resistance to TKIs, emphasizing the importance of this pathway.[177] In addition to SET, cancerous inhibitor of PP2A (CIP2A) was implicated in PP2A inhibition in CML and high CIP2A activity predicts a high risk of transformation to BP.[178]

The most salient feature of transformation from the chronic to the blast phase is the loss of terminal differentiation capacity. Rare patients acquire AML-type translocations such as *CBFβ-MYH11* at the time of transformation.[179] Mutant RUNX1 functions in a dominant-negative fashion to block neutrophil differentiation.[180] In the majority of M-BC patients, myeloid differentiation is impaired due to suppression of CAAT enhancer binding protein α (C/EBPα), which is the result of enhanced expression of the RNA-binding protein heterogeneous nuclear ribonucleoprotein E2 (hnRNP-E2), which inhibits C/EBPα translation. Two mechanisms underlie the increased expression and activity of hnRNP-E2. First the increase in BCR-ABL1 activity promotes expression of hnRNP-E2.[181] Second, miR-328, which binds to hnRNP-E2 to block its activity, is downregulated.[182] Disruption of other myeloid transcription factors such as C/EBPβ and over-expression of MECOM (EVI-1) have also been implicated in blastic transformation.[183–185] With the loss of differentiation capacity, the organization of CML hematopoiesis is disrupted, as granulocyte-macrophage progenitor cells acquire self-renewal capacity, possibly by activation of nuclear β-catenin, undermining the hierarchical structure of chronic phase hematopoiesis.[186] Various mechanisms have been implicated in β-catenin activation, including stabilization by BCR-ABL1 tyrosine phosphorylation, inactivation of glycogen synthase kinase 3β by mis-splicing, and activation of MNK family kinases.[187–189] Transformation to L-BC, which has almost invariably a pre-B-cell phenotype, is caused by inactivation of transcription factors that are critical for orderly B-cell development, such as IKZF1 or PAX-5. It is thought that physiologically these transcription factors impose a metabolic restraint on developing B cells that limits the risk of malignant transformation during antigen receptor diversification.[166] Interestingly the types of structural rearrangements in L-BC suggest that they originate from aberrant RAG-mediated recombination.[145]

The variability of somatic mutations associated with blastic transformation is consistent with conversion of multiple aberrancies into a relatively uniform phenotype. Recent work using multiple genome-wide "omic" platforms has implicated epigenetic dysregulation as the overarching mechanism. Specifically downregulation of polycomb repressive complex 2 (PRC2) and upregulation of PRC1 activity may explain phenotypic conversion despite heterogeneous upstream mutations.[174] In this framework, histone and DNA methylation work hand in hand to achieve profound epigenetic reprogramming, consistent with the frequent mutation of epigenetic regulators observed in multiple studies.[159,160] PRC2 directs BP DNA hypermethylation, which in turn silences key genes involved in myeloid differentiation and tumor suppressor function through epigenetic switching, while PRC1 represses an overlapping and distinct set of genes, including BP tumor suppressors. This may provide a rationale for therapeutic opportunities that are broadly applicable, for instance the combination of EZH2 (PRC2) and BMI1 (PRC1) inhibitors.

MOLECULAR BASIS OF TYROSINE KINASE INHIBITOR RESISTANCE

TKI resistance is classified as primary resistance (failure to achieve a desired response) and acquired resistance (loss of response). Mechanistically TKI resistance broadly bifurcates into BCR-ABL1–dependent resistance (reactivation of BCR-ABL1 kinase activity) and BCR-ABL1–independent resistance (resistance despite continued suppression of BCR-ABL1 kinase activity). Interestingly, for unknown reasons, a given CML case tends to re-use the same strategy to escape the next line of therapy, i.e. to acquire yet another BCR-ABL1 mutation if it has used this strategy before.[190] From a clinical standpoint the distinction between BCR-ABL1–dependent and –independent resistance is critical for rationalizing salvage strategy. (See box on Resistance, Relapse, Recurrence, Intolerance.)

RESISTANCE, RELAPSE, RECURRENCE, INTOLERANCE

Resistance implies the failure to achieve a desired level of response (primary resistance) or the loss of response while on therapy (secondary or acquired resistance). Relapse is used synonymously with acquired resistance, while the term recurrence is reserved (and should be used) to denote increasing leukemia burden in the context of treatment-free remission (i.e., off TKI therapy). Keeping the semantics clear is important, given that the biology and prognostic impact of relapse and recurrent are vastly different. In practice it can be challenging to distinguish between true (biological) resistance and resistance due to insufficient dose intensity because of intolerance.

BCR-ABL1–Dependent Tyrosine Kinase Inhibitor Resistance

The most common mechanism of BCR-ABL1 reactivation is mutations in the kinase domain of BCR-ABL1 that impair drug binding through steric hindrance or by stabilizing a kinase conformation from which a given inhibitor is excluded.[32,191,192] The spectrum of mutations conferring clinically relevant resistance is broadest for imatinib, reflecting its relatively low potency. Hot spots include the ATP binding loop (p-loop), activation loop, and threonine 315, which controls access to a hydrophobic pocket in the catalytic site and is frequently referred to as the gatekeeper residue (Fig. 69.8).[193] Compared to

Genome Biol. 2014;15[9]:461.)*

imatinib, second-generation TKIs exhibit a much more contracted spectrum of resistance mutations, and in aggregate cover all clinical mutations except T315I. This is due to the fact that all first- and second-generation TKIs make a hydrogen bond with T315 and require access to the hydrophobic pocket. In contrast, ponatinib skirts T315I through a rigid triple carbon bond.[194] Kinase domain mutations are more common in acquired resistance than in primary resistance and in AP/BP-CML than in CP-CML.[195] BCR-ABL1 genotyping is part of a workup for clinical resistance, as detection of a mutation allows rationalizing TKI selection. One should bear in mind that the value of genotyping is mostly to avoid selecting an inactive TKI, while the presence of a "sensitive" mutation does not guarantee a clinical response, indicating that other mechanisms, including BCR-ABL1 independent pathways, contribute to clinical resistance.[192] Studies in cell lines have implicated overexpression of BCR-ABL1 by gene amplification or transcriptional upregulation, but the importance of these findings for clinical resistance is less clear.[196] All TKIs are substrates for various efflux pumps, including ABCB1 (MDR1), and several polymorphisms have been correlated with the depth of response.[197] One study showed that overexpression of MDR1 may be sufficient to protect CML stem and progenitor cells, until they acquire a BCR-ABL1 kinase domain mutation that is able to drive overt resistance.[198]

BCR-ABL1–Independent Resistance

Extrinsic or intrinsic activation of growth and survival mechanisms can substitute for BCR-ABL1 kinase activity. Multiple different pathways have been implicated, including several that are also downstream effectors of BCR-ABL1, such as PI3K and MAPK.[192] This is consistent with the observation that TKI resistant CML is phenotypically still CML. The mechanistic heterogeneity of BCR-ABL1–independent resistance implies that no obvious universal therapeutic vulnerabilities exist, presenting a challenge for the development of rational therapeutic strategies. There is extensive overlap in the pathways involved in transformation to AP/BP and BCR-ABL1–independent resistance, both of which employ sweeping epigenetic reprogramming, e.g., through imbalanced activity of PRC1 and PRC2.[174] Such common denominator may in the future inform rational strategies to overcome BCR-ABL1–independent resistance. In reality, many cases of advanced TKI-resistant CML combine BCR-ABL1–dependent and –independent mechanisms, which explains why deep responses in these patients are difficult to achieve.

DIAGNOSIS AND INITIAL WORKUP

Clinical Evaluation

Signs and Symptoms

A complete history and physical exam are mandatory. CML may present with a plethora of constitutional symptoms such as fatigue, weight loss, fever, night sweats, and musculoskeletal aches. Severe constitutional symptoms raise concerns about advanced disease. Splenomegaly may cause abdominal pain and fullness; excruciating, sharp pain should raise suspicion of a splenic infarct or rupture, rare but potentially life-threatening CML complications.[199] Excessively high white blood cell counts can lead to leukostasis, especially in case of a high proportion of blasts in the differential. Clinically leukostasis may manifest as priapism, chest pain, respiratory compromise, neurological deficits, or visual impairment. Physical exam may reveal splenomegaly and sometimes hepatomegaly, while involvement of other extramedullary sites is uncommon. Spleen size (in cm below the left costal margin in the mid-clavicular line) must be documented. Despite its inaccuracy, this simple clinical test has remained a component of most CML risk scores.[200–202] Extramedullary disease other than hepatosplenomegaly is uncommon at presentation, and if suspected must be verified histologically. Some reactive lymphadenopathy may occur, but significant lymph node enlargement requires a biopsy to rule out blastic transformation. An immature cellular infiltrate (chloroma) indicates blast phase, but if there is differentiation it can be difficult to distinguish between true extramedullary disease from an inflammatory process that recruits CML cells. There are no signs or symptoms that are pathognomonic for CML. In developed countries, many patients are diagnosed incidentally, when an abnormal complete count blood obtained for an unrelated reason leads to a diagnostic workup.

Laboratory Manifestations

Complete Blood Count (CBC)

Standard hematologic parameters typically show leukocytosis, frequently thrombocytosis, and commonly mild anemia. The diagnosis of CML is usually suspected based on the morphology of a Wright- or Giemsa-stained blood smear. Granulopoiesis is left-shifted and may encompass the full spectrum of granulocytic precursors including blasts and promyelocytes. Basophilia is typical and a useful hint to distinguish CML from other MPNs. Significant eosinophilia is rare and raises the question of an alternative diagnosis. A manual differential is good clinical practice, as some automated cell counters do not provide the percentage of promyelocytes and/or basophils, which are required to determine disease phase. As all risk scores to stratify CML-CP are based on pre-therapeutic data, it is important to document the counts before any therapy is initiated. Flow cytometry is indicated only if AP/BP is suspected. Difficulties can arise in cases of discrepancies between morphological and immunophenotypic blast counts based on CD34 expression. In ambiguous cases, morphological blast counts should take precedence over flow cytometry.

Bone Marrow Aspirate and Biopsy

The bone marrow is hypercellular with myeloid predominance and left shift and frequently basophilia. Abnormally small, monolobated megakaryocytes (micromegakaryocytes) are typical and there may be pseudo-Gaucher cells (Chapter 54) (large macrophages with foamy cytoplasm and a lobated eccentric nucleus) and harlequin cells (dysplastic eosinophils with metachromatic granules). It is essential to obtain bone marrow morphology at diagnosis, as failure to do so may miss AP/BP-CML and lead to under-treatment. Whether all patients should have a biopsy is debatable. We routinely perform a biopsy at diagnosis to identify the occasional patient with nests of blasts missed by cytology. This is particularly important in patients with an aggressive presentation and those with inadequate aspirates or dry taps. As with peripheral blood, flow cytometry is not routinely indicated.

Bone Marrow Karyotyping

Metaphase karyotyping of bone marrow cells using G- or R-banding is mandatory to confirm the diagnosis of CML (Chapter 57). As a rule, a minimum of 20 metaphase spreads is analyzed. More than 95% of CML patients are Ph$^+$, including ~5% of patients in whom Ph is part of complex translocations involving additional chromosomes. These complex translocations do not affect the outcome of patients on TKI therapy, and they must not be confused with clonal cytogenetic abnormalities in Ph$^+$ cells (CCA/Ph$^+$, also referred to as clonal cytogenetic evolution).[157] Rare (<5%) of patients have a silent Ph that is not identified by karyotyping, and molecular testing is required to establish the diagnosis of CML. A critical piece of information from karyotyping is CCA/Ph$^+$, since these patients have inferior progression-free and overall survival on TKI therapy, even in the absence of other features of AP/BP.[157,203,204]

Fluorescence In Situ Hybridization

Fluorescence in situ hybridization (FISH) uses fluorescent DNA probes that hybridize to *BCR* and *ABL*1 genetic regions adjacent to the translocation breakpoints—typically red fluorescence to label *ABL1* and green fluorescence to label *BCR*. Most FISH assays in current use identify both *BCR-ABL1* (on Ph) and *ABL1-BCR* fusion signals (on the derivative chromosome 9) and have low false-positive and -negative rates (Chapter 57).[205] In contrast to karyotyping, FISH is usually performed on interphase nuclei, which increases sensitivity as 200 to 500 nuclei can be analyzed routinely. FISH is an excellent test to establish the diagnosis of CML in cases of silent Ph, but it should not routinely replace karyotyping, as CCA/Ph$^+$ will be missed. Modern FISH probes also identify deletions in *ABL1* adjacent to the translocation breakpoint, which confer an adverse prognosis to patients treated with IFN and second-line imatinib, but not to patients on frontline TKI therapy.[56,57,206] Altogether, FISH at diagnosis does not add actionable information in addition to standard karyotyping and its routine use in addition to conventional karyotyping is not justified. However, as a negative result by FISH has a very high positive predictive value for a CCyR by karyotyping, FISH is an extremely useful test to monitor patients with atypical BCR-ABL1 transcripts that are not detected by standard qPCR assays.[207]

Reverse Transcription Polymerase Chain Reaction

Qualitative RT-PCR is used to identify a *BCR-ABL1* fusion mRNA in patients with suspected CML who are Ph$^-$ by metaphase karyotyping, essentially providing the same information as FISH. It is important to make sure that the assay detects all types of BCR-ABL1 transcripts, including rare atypical transcripts.[208] As most *quantitative* PCR assays are designed to detect the typical e13a2 (b2a2) and e14a2 (b3a2) transcripts, but will miss e1a2, e19a2, and atypical transcripts, qPCR is not suitable for ruling out CML. A more detailed discussion of qPCR for *BCR-ABL1* is provided in the section on monitoring response.

Myeloid Mutation Screening

NGS assays to screen for mutations in genes involved in myeloid malignancies have become part of the routine diagnostic work-up of patients with MPNs. Approximately one-third of patients with CP-CML have mutations in genes such as *TET2* and *ASXL1* at diagnosis, but the prognostic impact of these mutations has not been established.[159] NGS is currently not mandatory, as results do not typically inform clinical decisions, but this may change as more data become available. A reasonable approach in view of this uncertainty may be to consider NGS in high-risk CP-CML and AP/BP-CML patients.

Imaging

An abdominal ultrasound or computerized tomography (CT) scan is frequently performed at diagnosis and may reveal splenomegaly and/or hepatomegaly. Imaging studies are indicated only in patients where palpation of spleen and liver is not possible due anatomical barriers or in whom extramedullary involvement other than spleen and liver is suspected. Importantly, there is no easy conversion of spleen size measured by ultrasound or CT scan to the clinical measurement in centimeters under the rib cage, which is required for calculating risk scores. Altogether imaging as part of the routine CML workup is discouraged.

RISK STRATIFICATION

Disease Phases

CML progresses in stages termed chronic phase (CP-CML), accelerated phase (AP-CML), and blast phase (BP-CML). Various definitions of AP-CML and BP-CML are in use that are based on clinical, morphological, and cytogenetic features. Unfortunately, criteria are still mostly based on outcomes obtained in the pre-TKI era, and some lack any association with sufficiently powered studies. A major inconsistency is the proportion of blasts required to establish a diagnosis of blast phase. While ≥20% blasts are used by the WHO classification of hematologic neoplasm, the European Leukemia Net (ELN), National Comprehensive Cancer Network (NCCN), and Center for

International Blood and Marrow Transplant Research (CIBMTR) use a cutoff of ≥30%. A pragmatic approach is to use the definitions employed by major prospective TKI trials, which form the basis for current treatment algorithms (Table 69.3).[209] There is controversy regarding clonal cytogenetic evolution, i.e. the presence of additional cytogenetic abnormalities in the Ph$^+$ cell clone (CCA/Ph$^+$). There is agreement that acquisition of CCA/Ph$^+$ on treatment is diagnostic of AP-CML,[210] but this is not universally accepted for newly diagnosed patients, although recent studies showed that these patients have inferior outcomes even in the absence of any other features of AP-CML, raising the question of whether the criteria should be changed.[157,204] Failure of one or more TKIs is an ominous sign indicative of advanced CML, even in patients with CP-CML, but has not yet been integrated into the phase definitions.[40] Lastly molecular data support the existence of two, but not three distinct disease phases.[211,212] The hope is that more consistent criteria will be developed in the future that include relevant clinical and molecular findings, such as somatic mutations detected by NGS.[213]

TABLE 69.3 Definition of Accelerated and Blast Phase

Accelerated Phase[a]
15%–29% blasts in blood or marrow
Greater than 30% blasts plus promyelocytes in blood or marrow (provided <30% blasts are present)
≥20% peripheral basophils in the blood or marrow
Platelet counts <100 × 10^9/L, unrelated to therapy
Additional cytogenetic abnormalities in Ph$^+$ cells while on TKI therapy
Blast Phase[a]
≥30% blasts in blood or marrow
Extramedullary blast infiltrates

[a]At least one criterion must be satisfied.
TKI, Tyrosine kinase inhibitor.

The CP-CML blood smear is characterized by left-shifted granulocytosis with maintenance of terminal differentiation, frequently accompanied by basophilia and sometimes eosinophilia. Significant dysplasia raises the question of alternative diagnoses, such as atypical CML. Bone marrow aspirate and biopsy are hypercellular for age, but maturation is complete (Fig. 69.9A, B). Micromegakaryocytes are typical and an important diagnostic hint. Grade 1 to 2 reticulin fibrosis may be present, but severe fibrosis is uncommon and may be associated with poorer outcomes.[214] In the absence of effective therapy, CP-CML inexorably progresses to BP-CML within 2 to 3 years. BP-CML can exhibit a pre B-lymphoid (25%), myeloid (70%), or indeterminate (5%) phenotype[215] and develop suddenly or over a period of time through the intermediary stage of AP-CML (see Fig. 69.9C, D). In addition to a blast count of ≥30% in the blood or bone marrow, extramedullary myeloblasts (chloroma) in tissues other than liver or spleen define BP-CML, and any proportion of pre-B lymphoblasts strongly suggests lymphoid blast phase.

Risk Scores in Chronic Phase of Chronic Myeloid Leukemia

There are several prognostication systems designed to subclassify CP-CML (Table 69.4). The oldest system, reported by Joseph Sokal more than 35 years ago, uses a sophisticated formula based on age, blast count in the blood, platelet count, and spleen size (in cm below

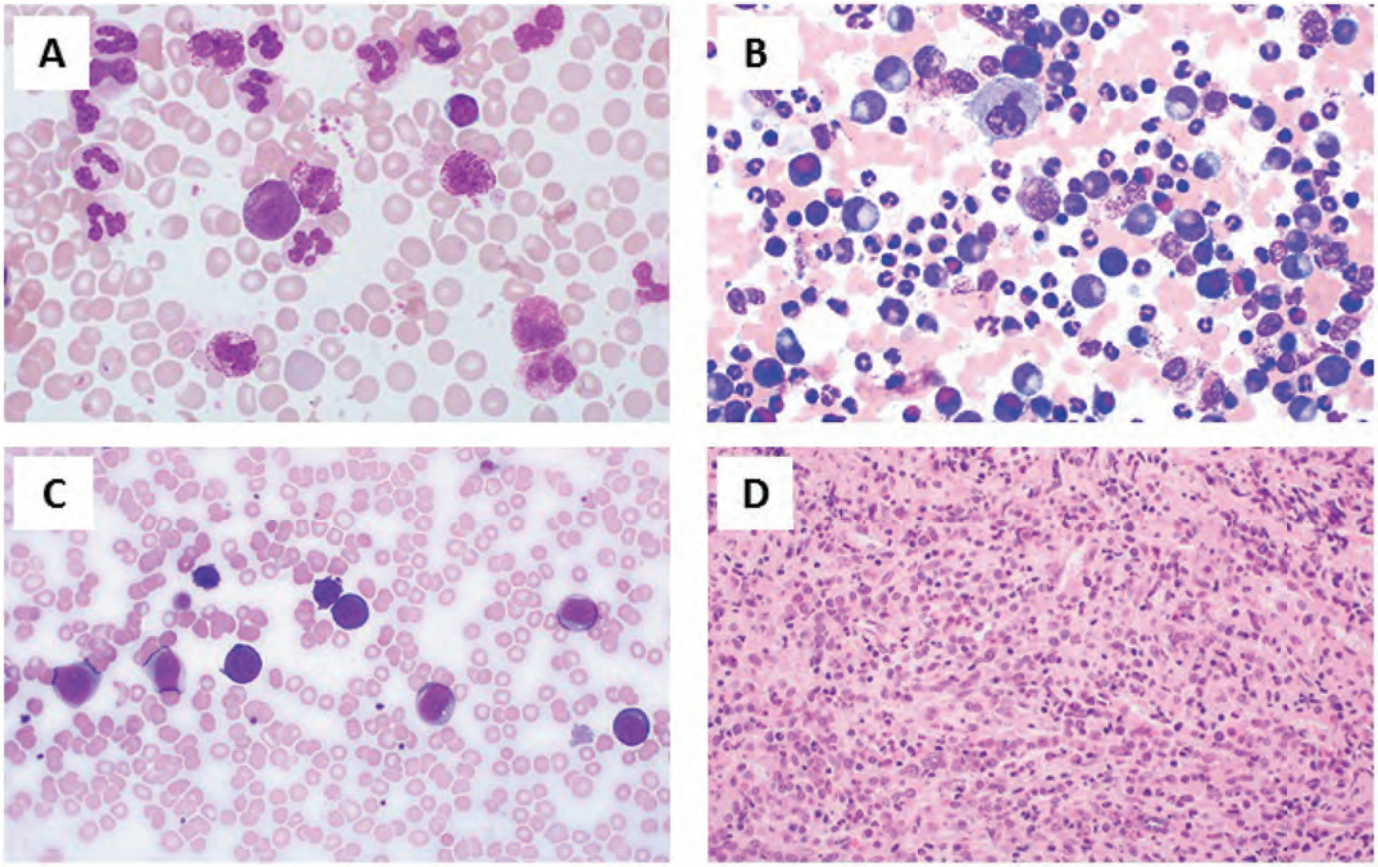

Figure 69.9 CHRONIC MYELOID LEUKEMIA MORPHOLOGY. (A) Blood smear, chronic phase. (B) Bone marrow aspirate smear, chronic phase. (C) Blood smear, blast phase. (D) Bone marrow biopsy, blast phase.

TABLE 69.4 Prognostic Scores in Newly Diagnosed Chronic Phase of Chronic Myeloid Leukemia

Score	Formula	
Sokal Sokal et al. 1984	Exp 0.0116 × (age − 43.4) + 0.0345 × (spleen − 7.51) + 0.188 × [(platelet count ÷ 700)^2 − 0.563] + 0.0887 × (myeloblasts − 2.10)	Low risk: <0.8 Intermediate risk: 0.8–1.2 High risk: >1.2
ELTS Pfirrmann et al. 2016	0.0025 × (age in completed years/10)^3 + 0.0615 × spleen size below costal margin + 0.1052 × blasts in peripheral blood + 0.4104 × (platelet count/1000)$^{-0.5}$	Low risk: ≤1.5680 Intermediate risk: 1.5680–2.2185 High risk: >2.2185

the left costal margin). Scores of less than 0.8, 0.8 to 1.2, and greater than 1.2 define low, intermediate, and high risk.[200] Although the Sokal score was built on patients treated with busulfan-based chemotherapy, it proved resilient to changes in the treatment paradigm and has been applied successfully to risk-stratify patients treated with IFN or TKIs.[216,217] Subsequently, Hasford developed a score optimized for patients on IFN.[201] Recently, a third prognostication system (EUTOS score) optimized for patients on imatinib was reported.[202] The EUTOS score is simple, relying on basophils and spleen size only, but since an independent study failed to validate the score, its use is not recommended.[218] An important advance is the EUTOS long-term survival score (ELTS), which takes into account the fact that most CML patients with access to TKIs and appropriate monitoring die from non-CML causes.[219] Although reliant on the same parameters as the Sokal score, the ELTS was superior to all other scores in predicting CML-related death in CP-CML patients treated with imatinib, and its use is recommended in this population. Data on second-generation TKIs are not yet available. As with the definitions of disease phases, molecular markers may eventually replace clinical risk scores.[213]

DIFFERENTIAL DIAGNOSIS

Other MPNs, including atypical CML, CMML, chronic neutrophilic leukemia, MPN associated with rearrangements within the platelet *PDGFRs*, or fibroblast growth factor receptor 3 (*FGFR3*) can mimic CML clinically and morphologically. Conversely, CML patients may present with features indistinguishable from essential thrombocythemia (ET) or primary myelofibrosis. It is therefore mandatory to ascertain the presence or absence of *BCR-ABL1* in every patient with MPN to prevent misdiagnosis with potentially catastrophic consequences. Demonstration of Ph or *BCR-ABL1* establishes the diagnosis of CML in a patient with MPN, irrespective of other clinical, morphological, or genetic features. Tests like vitamin B12 levels (high in CML) or the leukocyte alkaline phosphatase (LAP) score (low in CML, high in leukemoid reactions) are of historical interest only. CML may present in BP and these cases can be extremely difficult to distinguish from de novo Ph$^+$ ALL or Ph$^+$ AML, a rare and sometimes disputed entity.[220] In the pre-TKI era, such patients were treated with multi-agent chemotherapy, and upon count recovery the underlying CML often became evident by typical morphology and the continued presence of Ph. With all BCR-ABL1-positive patients receiving TKIs up front, this accidental diagnostic test is no more valid. Preceding CP-CML may be suspected if there are residual left-shifted but maturing granulocytic precursors, basophilia, and splenomegaly. Given that the therapeutic approaches are almost identical, the distinction is mainly of academic interest. A *BCR* breakpoint in the m-*BCR* with e1a2 *BCR-ABL1* transcript establishes a diagnosis of Ph$^+$ ALL for all practical purposes.

MONITORING RESPONSE TO THERAPY

Response to therapy is assessed by clinical, hematological, cytogenetic, and molecular parameters that reflect the decrease of leukemia burden (Fig. 69.10A). Response to TKI therapy is highly predictive of subsequent outcome, and milestones of response have been identified by NCCN and ELN consensus panels (see Fig. 69.10B).

Hematologic Response (CHR)

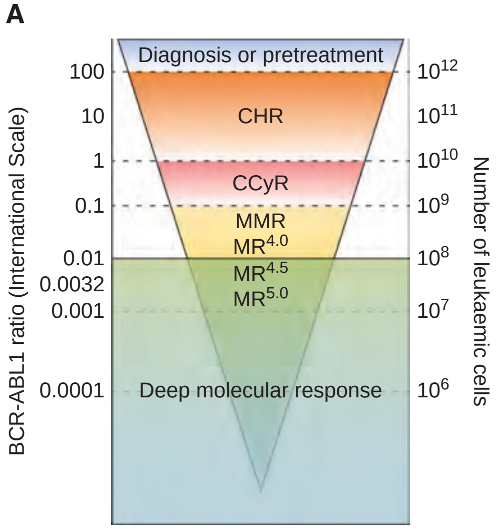
Complete hematologic response (CHR) is defined as the resolution of all CML-related signs and symptoms (including palpable splenomegaly) and normalization of white blood cell count, white blood cell differential, and platelet count. Normalization of hemoglobin is not part of the CHR definition. Of note, bulky splenomegaly is often slow to resolve and the significance of persistent minimal splenomegaly in patients who meet all other CHR criteria is unknown. The term "major hematologic response" (MHR) denotes a situation where blasts are absent from the blood and less than 5% in the bone marrow, but reconstitution of peripheral blood counts has not occurred. Although MHR was used as an endpoint in some clinical trials, its prognostic significance is unknown.

Cytogenetic Response

Bone marrow karyotyping was the first method used to assess restoration of normal (polyclonal) hematopoiesis. Since karyotyping is laborious and time consuming, a minimum of 20 metaphases was set as the standard to provide reasonable response definitions despite a limited sample. The 95% confidence intervals of correctly identifying 50% Ph$^+$ metaphases are 35% and 65%. Therefore a partial cytogenetic response (PCyR) was defined as 35% or less Ph$^+$ metaphases, reflecting 50% or less Ph$^+$ metaphases with 95% confidence. CCyR denotes the absence of Ph$^+$ metaphases, and CCyR and PCyR combined are referred to as major cytogenetic response (MCyR). Some studies also report minor (36% to 65% Ph$^+$) and minimal (66% to 95% Ph$^+$) cytogenetic responses, but these response levels have minimal clinical significance, since correlations with outcome are weak or absent. Given the strong correlation between CCyR and overall survival, MCyR and PCyR are of mostly historical interest and should be avoided as an efficacy endpoint in clinical trials.

Molecular Response

qRT-PCR for *BCR-ABL1* has emerged as the assay of choice for monitoring patients on TKI therapy or after allogeneic stem cell transplantation (SCT). In the past, the use of numerous technical platforms by commercial vendors and academic labs had created a confusing landscape, where results could not be compared between labs and with data from clinical studies. Following an initial consensus meeting, a multi-center collaboration led to the introduction of the international scale (IS) as a universal metric to express *BCR-ABL1* transcript levels.[221] In principle results from any qRT-PCR assay with linear performance characteristics over a sufficiently large range can be converted to IS units by using an assay-specific conversion factor. An exhaustive technical discussion of qRT-PCR monitoring is beyond the scope of this chapter and the reader is referred to comprehensive reviews of the subject,[221] but a few critical points deserve mentioning. First, compared to metaphase karyotyping and FISH, qPCR has a vastly greater dynamic range, which can span up to 5 logs. However, this sensitivity is reached only if the sample is of optimal quality. Thus, laboratories must report the sensitivity reached for a given sample to allow for correct interpretation of results. Second, not all housekeeping genes are equally suitable as control genes for normalization of RNA input; acceptable choices include *ABL1*, *BCR*, *GUS*, and *G6PD*.[221] β-actin is not acceptable due to high-level expression that may conceal degradation of the sample. Third, in clinical practice it is



B

BCR-ABL1 (IS)	3 months	6 months	12 months
>10%	YELLOW	RED	
>1%–10%	GREEN		YELLOW
>0.1%–1%	GREEN		LIGHT GREEN
≤0.1%	GREEN		

Figure 69.10 (A) Response to treatment and residual leukemia in chronic myeloid leukemia. *CHR*, Complete hematologic response; *CCyR*, complete cytogenetic response; *MMR*, major molecular response; *DMR*, deep molecular response. *(Adapted from O'Hare T, Zabriskie MS, Eiring AM, et al. Pushing the limits of targeted therapy in chronic myeloid leukaemia*. Nat Rev Cancer. *2012;12[8]:513–526.)* (B) Milestones of response to first line TKI therapy. Green is considered optimal, and no change to therapy is required. Yellow indicates a suboptimal response or 'warning,' which may trigger more intense monitoring or efforts to increase compliance, but not necessarily a change of treatment. Red denotes treatment failure, warranting a diagnostic workup and change of therapy.

often necessary to decide whether a rise of *BCR-ABL1* mRNA is real and should trigger a more extensive workup. The most important factor is the quality of the test, which determines the extent of inter-test variation and, as such, the optimal compromise between sensitivity and specificity.[222] Current recommendation is that a 5- to 10-fold rise in transcript levels be regarded as significant.[221] In excellent laboratories this may decrease to twofold,[223–226] while in poor laboratories even 10-fold rises may not be dependable. For the clinician, it is important to know the performance of the laboratory and to adjust standard operating procedures accordingly. It is good clinical practice to repeat the test in case of rising *BCR-ABL1* mRNA levels before rushing to far-reaching conclusions, particularly if the changes occur at a low level, where the coefficient of variation is largest. Fourth, key anchoring points of the IS are 100%, which is equivalent to the average *BCR-ABL1* mRNA expression of 30 patients treated on the International Randomized Study of Interferon and STI571 (IRIS) study[227] and 0.1%, corresponding to a 3-log reduction compared to this baseline and referred to as MMR. Achievement of MMR on TKI therapy is an important milestone that portends a good prognosis. Further reductions of *BCR-ABL1* mRNA by 4 or 4.5 logs are referred to as MR^4 or $MR^{4.5}$, respectively. $MR^{4.0}$ is frequently referred to as DMR and is the minimum depth of response required to consider a trial of TFR. It is important to be aware that the fold reductions of *BCR-ABL1* expressed on IS refer to a standardized baseline rather than the patient's individual baseline, thus representing an absolute measurement of leukemia burden. If results expressed on some obscure percentage scale are mistaken as IS results, response may be overestimated, giving false reassurance. Fifth, in the past a complete molecular response (CMR) was defined as negativity for *BCR-ABL1* mRNA. However, in contrast to MMR, which is an absolute value due to its anchoring to a standardized baseline, a universal definition of CMR is impossible, as it depends on the sensitivity of the assay and the quality of the sample. As such the term CMR should be abandoned altogether.

Despite universal agreement that standardized testing is superior, and years of education, some commercial labs in the US still do not express results on the IS. These assays are out of date, and should not be covered by insurance carriers. New technologies have refined the quantification of BCR-ABL1 on several levels. Digital PCR is based on amplification in single wells and Poisson statistics to estimate transcript numbers. Sensitivity is increased by 0.5 to 1 log compared to conventional assays. DNA-based assays require individualized primer design due to the variation in genomic breakpoints, but achieve 1-log higher sensitivity.[228] Other improvements include automated point of care assays that do not require sample processing in a laboratory, avoiding the need for shipment. Amplification systems that function without temperature cycling will further reduce infrastructure requirements. Technological advances of this kind will hopefully lead to greater access to PCR-based diagnosis and monitoring in resource-deprived countries.

BCR-ABL1 Mutation Testing

BCR-ABL1 mutations are the most extensively characterized mechanism of TKI resistance. The current NCCN guideline is to test for mutations in patients with failure to achieve therapeutic milestones or with relapse or progression to AP/BP-CML on therapy. Mutation analysis at baseline in patients with AP/BP-CML is not indicated due to the low yield and the absence of prospective studies supporting therapy modification based on the results. Similarly, routine mutation surveillance in high-risk patients is not indicated. For a long time Sanger sequencing of *BCR-ABL1* amplicons had been the gold standard of mutation screening, although it has limited sensitivity (20% to 30% mutant allele).[221] Several technologies such as high performance liquid chromatography, Sequenom MassARRAY, and allele-specific PCR were optimized to detect specific *BCR-ABL1* mutations with higher sensitivity. Since most of these studies were retrospective, it was difficult to assess the clinical significance of low-level mutations, and it remained controversial whether a positive test result should trigger a change of therapy.[185,186,229] Recently NGS has emerged as a technology that reliably increases sensitivity to between 1% and 5%, depending on sequencing depth. A recent Italian multi-institutional study demonstrated that NGS testing for BCR-ABL1 mutations is feasible and cost-effective in a routine setting. Confirming prior results, the study showed that mutant clones are invariably selected if the patient is treated with a TKI that is inactive against the mutant in question.[230] Even in the absence of a survival endpoint, it seems common sense to avoid exposing any patient to an ineffective therapy. In the future, error-corrected NGS may allow for ultra-sensitive mutation detection.[231] As with all other biomarkers, the clinical significance of such very small clones must be validated. Compound mutations, that is, the presence of two or more mutations in the same BCR-ABL1 molecule, add another level of complexity. If the variant allele frequencies add up to more than 100%, the presence of a compound mutation can be inferred. If the mutations are in close proximity, they may be covered in the same NGS amplicon. However, in many cases, sequencing of individual PCR clones is required to confirm the presence of a compound mutation. Clinically, many compound mutations, particularly those including the *BCR-ABL1*^{T315I} "gatekeeper" mutation, confer high level resistance to most or all currently approved TKIs and are associated with poor prognosis.[97,232]

THERAPY

Cytotoxic Agents

The alkylating agent busulfan was the first drug that effectively controlled white blood cell and platelet counts, but is rarely used today except as part of conditioning regimens for HCT.[20] Busulfan is highly toxic to HSCs, and must be dosed with great caution due to delayed myelosuppression. Chronic busulfan exposure is associated with pulmonary fibrosis, and proper dosing can be challenging due to prolonged cytopenias. Hydroxyurea is a ribonucleotide reductase inhibitor currently used as an effective method for lowering excessive white blood cell counts until the diagnosis of CML is confirmed. Although at conventional doses hydroxyurea acts predominantly on more mature progenitor cells, and myelosuppression is usually short-lived and reversible, overzealous WBC cosmetics is counterproductive. Prolonged cytopenias can result, particularly if aggressive hydroxyurea therapy is followed by a TKI, which not only puts the patient at risk of bleeding and infection, but may impair response to TKIs due to prolonged dose interruptions. In general practice, the only solid indication to rapidly lower the WBC is clinical signs of leukostasis, such as retinal ischemia, hypoxia, or priapism.

Interferon-α

IFN was introduced as a CML therapy in the early 1980s. Initial reports of CHR were followed by the surprising observation of CCyR in some cases, although only in a small minority of patients. The biological basis for IFN-induced responses has been the subject of much research, but to date the mechanism remains elusive, with evidence supporting cytotoxic, differentiating, and immunomodulatory effects. Subsequent studies combined IFN with cytarabine and found the combination superior to IFN monotherapy. Prior to the introduction of TKIs, IFN/Ara-C was the gold standard for drug therapy of CML.[233,234] Pegylated IFN formulations were a major improvement, due to better tolerability and the convenience of weekly injections. Today IFN remains an option for the rare patients who are intolerant of all TKIs. Moreover, IFN is a safe and frequently effective strategy to maintain responses in women who wish to become pregnant.[235] Lastly, combining TKIs with IFN improves the depth of molecular responses,[236] and IFN maintenance may increase the stability of TFR.[237]

Omacetaxine

Omacetaxine (previously homoharringtonine) is a subcutaneously administered protein synthesis inhibitor approved for the treatment of CP-CML and AP-CML with resistance to at least two TKIs. In CP-CML, the rate of MCyR was 18.4%, with a median duration of 12.5 months.[238] Due to the inconvenience of administration and significant myelosuppression, omacetaxine is used infrequently, but is an option as a palliative strategy for patients with intolerance of or resistance to all TKIs.

Tyrosine Kinase Inhibitors

TKIs are the standard of care for newly diagnosed CML patients in all disease phases. Six TKIs are currently approved—imatinib, dasatinib, nilotinib, bosutinib, ponatinib, and radotinib (only in South Korea). The first in class inhibitor imatinib is referred to as a first-generation (1 G) TKI; dasatinib, nilotinib, bosutinib, and radotinib are second-generation (2 G) TKIs; and ponatinib is a third-generation TKI. The TKIs are distinct based on their potency, activity against *BCR-ABL1* mutants, spectrum of activity against kinases other than *BCR-ABL1*, and side effect profiles. Today' treatment algorithms are based on a series of phase 3 trials (Table 69.5).

Imatinib

A phase 1 trial of imatinib initiated in 1998 included CML patients in all disease phases who had failed conventional therapy. Activity was seen across the spectrum, including CCyR, although mainly in CP-CML.[27,28] No maximum tolerated dose (MTD) was identified, and a phase 2 dose of 400 mg daily was selected based on the cytogenetic responses. These trials in CP-, AP-, and BP-CML confirmed or exceeded the phase 1 results and led to rapid approval of imatinib for patients who had failed prior IFN therapy due to resistance or intolerance.[239–242] Responses in CP-CML were mostly durable, but there was a high rate of resistance in advanced CML, which prompted an increase of the starting dose to 600 mg imatinib daily. The IRIS study compared imatinib 400 mg daily versus a combination of IFN and cytarabine, and found imatinib to be vastly superior in all major endpoints, but most importantly in progression-free survival.[242] Crossover was permitted for resistance or intolerance and occurred almost exclusively in patients failing IFN, and the fact that many of these patients were effectively salvaged by imatinib may explain why no difference in overall survival between the two experimental arms has been observed.[244] At the last follow-up at 10 years, the estimated overall survival of patients started on first-line imatinib was 83.3% (95% CI, 80.1 to 86.6).[245] Considering that overall survival of CML patients in the pre-TKI era was approximately 5 years, it is evident that imatinib revolutionized CML therapy, turning a lethal condition into a manageable ailment for the majority of patients. Subsequent phase 3 studies of imatinib in newly diagnosed CP-CML patients mainly addressed dose optimization and the role of combining imatinib with IFN or cytarabine. Single-arm/single-center studies in comparison with historical controls had suggested higher rates of CCyR and MMR for 800 mg imatinib daily, commonly referred to as high-dose imatinib.[246,247] Two prospective randomized studies compared 400 mg vs. 800 mg imatinib in patients with newly diagnosed CP-CML. The Tyrosine Kinase Inhibitor Optimization and Selectivity Study (TOPS) included patients from all Sokal risk groups, while an Italian trial focused on high Sokal risk patients. Both studies failed in their primary endpoints, MMR or CCyR at 12 months, respectively.[248,249] The German CML IV study reported superior rates of MMR at 12 months for 800 mg compared to 400 mg imatinib daily (59% vs. 44%, $P < .001$), but there was no difference in progression-free survival.[250,251] Interestingly, in this study, imatinib dosing was flexible and was maximized based on the individual patient's tolerability, resulting in a median dose of 627 mg imatinib daily. Similarly, the French SPIRIT study reported higher MMR rates at 12 months (49 vs. 38%) for patients treated with 600 versus 400 mg imatinib daily.[236] Thus, the optimal dose of imatinib may be approximately 600 mg daily, equal to the recommended dose for AP/BC.[252]

Dasatinib

A phase 1 study tested dasatinib in CML patients who had failed prior imatinib. Activity was seen in all disease phases.[33] Subsequent phase 2 studies tested different doses and dosing schedules.[253–257] Contrary to expectations based on dasatinib's short plasma half-life of 3 to 5 hours, once daily dosing proved to be equally effective compared to twice daily dosing, but was better tolerated, and 100 mg dasatinib once daily for CML-CP, and 140 mg once daily for AP/BP-CML emerged

TABLE 69.5 Results of Major Frontline Studies in Patients With Newly Diagnosed Chronic Phase of Chronic Myeloid Leukemia

Trial	Treatment	N =	CCγR	MMR	$MR^{4.5}$	TFS	OS
IRIS (18 months)	IM 400 mg/day	553	74% (est. at 18 months)	57% (est. at 12 months)[a]	NA/NR	96.7% (at 18 months)	97.2% (est. at 18 months)
IRIS (18 months)	IM 400 mg/day	553	74% (est. at 18 months)	57% (est. at 12 months)[a]	NA/NR	96.7% (at 18 months)	97.2% (est. at 18 months)

as the recommended doses. In laboratory studies, 4 hours of dasatinib exposure was sufficient to reduce colony formation by primary CML and irreversibly commit CML cell lines to apoptosis.[258] Collaborative group (SWOG S0325) and industry-sponsored (DASatinib versus Imatinib Study In treatment-Naive CML patients, DASISION) phase 3 studies compared dasatinib 100 mg daily with imatinib 400 mg daily in newly diagnosed CML-CP patients. Dasatinib proved superior in the primary endpoint, CCyR at 12 months.[257,259] Progression to AP/BP-CML was reduced, but the difference did not reach statistical significance, and no differences in overall survival were observed. Based on the results of DASISION, dasatinib was approved for use in newly diagnosed CML patients.

Nilotinib

A phase 1 study of nilotinib in a cohort of CML and Ph$^+$ ALL patients who failed prior imatinib therapy revealed considerable activity in CP-CML and AP-CML, while results in BP were less impressive.[34] Based on the confirmatory results in phase 2 studies, nilotinib 400 mg twice daily was approved for second-line therapy of CP-CML and AP-CML.[260,261] Although the phase 2 results for BP-CML are comparable to those of dasatinib, nilotinib is not currently approved for this indication.[262] The Evaluating Nilotinib Efficacy and Safety in Clinical Trials–Newly Diagnosed (ENESTnd) study evaluated nilotinib (300 or 400 mg twice daily) in comparison with imatinib 400 mg daily in first-line therapy of newly diagnosed CP-CML. Both experimental arms were superior to the standard arm in the major endpoint, MMR at 12 months.[263] Unlike any other second-generation TKI, nilotinib significantly improved progression-free survival. Based on the ENESTnd results, nilotinib (300 mg twice daily) received approval for frontline therapy of CML-CP. The 5-year follow-up of the study confirmed the superior rates of molecular responses. Progression free survival was improved for both experimental arms, and overall survival for the nilotinib 400 mg twice daily arm.[264]

Bosutinib

Formerly known as SKI-606, bosutinib was initially approved at a dose of 500 mg daily for third-line therapy (after failure of imatinib and one second-generation TKI) of CML in all phases.[265,266] A phase 3 trial (Bosutinib Efficacy and Safety in Newly Diagnosed Chronic Myeloid Leukemia, BELA) comparing bosutinib 500 mg daily vs. imatinib 400 mg daily as frontline therapy for CP-CML failed to meet its primary endpoint, CCyR at 12 months. Regulatory approval was denied despite superior rates of MMR.[267,268] It was speculated that inadequate management of adverse events led to a high rate of discontinuation in the experimental arm, including patients who discontinued bosutinib before their first response assessment. A second phase 3 study using a reduced dose of bosutinib at 400 mg daily (Bosutinib Trial in First-Line Chronic Myelogenous Leukemia Treatment BFORE) demonstrated superiority for MMR at 12 months (47.2 [40.9 to 53.4] vs. 36.9 [30.8 to 43.0]%). Overall and progression free survival were not different.[269] Based on the BFORE study, bosutinib became the fourth TKI approved for the first-line therapy of CP-CML.

Ponatinib

In aggregate, first- and second-generation TKIs cover all single BCR-ABL1 mutants, with the exception of BCR-ABL1^{T315I}.[270] Ponatinib was designed to address this specific need. Unlike other approved TKIs, ponatinib skirts isoleucine 315 through a carbon–carbon triple bond and exhibits potent activity against native BCR-ABL1 and all single mutants.[194] Based on its long half-life and prolonged target occupancy time, ponatinib is considered the most potent BCR-ABL1 TKI currently approved. However, this potency comes at the expense of reduced selectivity, and multiple additional tyrosine kinases are inhibited at clinically relevant plasma concentrations.[271] Ponatinib at an initial dose of 45 mg daily was effective in CML patients in all phases and Ph$^+$ ALL patients who had failed at least two prior TKIs or had the BCR-ABL1^{T315I} mutation.[272,273] Responses were generally durable in CP-CML, less stable in AP-CML, and transient in BP-CML and Ph$^+$ ALL. A strong cardiovascular safety signal emerged with longer follow-up of the Ponatinib efficacy and safety in Philadelphia chromosome-positive leukemia (PACE) study, leading to premature termination of an ongoing phase 3 trial [Ponatinib versus Imatinib in Chronic Myeloid Leukemia (EPIC)].[274] It was initially thought that ponatinib's vascular toxicity was caused by inhibition of vascular system kinases such as VEGF, PDGFR, and TIE2. Recent work in mice revealed that ponatinib-induced vascular toxicity involves VWF-mediated platelet adhesion and a secondary microvascular angiopathy that produces ischemic cardiac motion abnormalities with angiographically normal coronary arteries. Interventions known to reduce VWF multimer size mitigated toxicity.[275] There is evidence that ponatinib toxicity is dose-dependent, leading to the recommendation of dose reduction as soon as a response has been achieved. A dose-finding study compared starting doses of 45, 30, and 15 mg ponatinib daily, with mandatory dose reduction to 15 mg daily upon achieving BCR-ABL1 <1%. Responses were best for the 45 mg daily starting dose, with mostly comparable toxicity between arms. Cardiovascular events were lower compared to the PACE study.[276]

Drug Combinations

Imatinib has been tested in combination with multiple cytotoxic agents and signal transduction inhibitors, mostly in the setting of TKI resistance or AP/BP-CML. In the frontline setting, data are limited to combinations with cytarabine or IFN. Imatinib at 400 mg daily was compared with 600 mg daily as well as 400 mg daily combined with pegylated IFN or cytarabine, with MMR at 12 months as the major endpoint.[236] Patients in the IFN/imatinib arm had significantly higher rates of MMR than all other arms of the study (57% vs. 38% at 12 months for the comparison with single agent imatinib). Importantly, these data were confirmed by a smaller Scandinavian study.[277] Thus far, no differences in overall and progression-free survival have been seen, and IFN/imatinib combinations should be considered experimental. Imatinib and other TKIs were combined with AML-type multiagent chemotherapy in patients with myeloid BP, and with ALL-type chemotherapy in patients with lymphoid BP, with acceptable toxicity. Imatinib also demonstrated activity when combined with hypomethylating agents in TKI-resistant CML.[278] Unfortunately all these studies were single-armed, and the evidence supporting the addition of chemotherapy to TKIs is limited.

Allogeneic Stem Cell Transplantation

Prior to the introduction of imatinib, HCT was recommended to all eligible patients, and even today it is still regarded by some as the only therapy with curative potential. CML is more susceptible to immunotherapy in an HCT setting than most hematologic cancers and HCT was the first treatment modality that restored Ph$^-$ hematopoiesis and induced durable responses in CML.[22] Donor leukocyte infusions (DLIs) were first used in CML patients, demonstrating their effectiveness and proving the existence of a graft-versus-leukemia effect.[279] Unfortunately the transplant field is plagued by a paucity of controlled trials and only one single study prospectively compared HCT vs. drug therapy for CML. In this study, newly diagnosed patients with CML-CP were biologically randomized to a matched sibling transplant vs. IFN-based drug therapy, the best drug therapy available when the trial was initiated.[280] Initially patients managed with IFN had superior survival, with the biggest difference observed in patients with low Sokal risk. However survival curves crossed after approximately 8 years, suggesting that transplant would be superior in the long run if IFN was the alternative. In view of the efficacy of TKIs in the frontline setting, and the fact that early transplant-related mortality is higher than the risk of early disease progression, allotransplant is no longer justified in newly diagnosed patients with CML-CP.[210]

The European Group for Blood and Marrow Transplantation (EBMT) developed risk scores for allografting in CML and identified disease duration of greater than 12 months, advanced disease, higher age, unrelated donor type, and the combination of a male recipient with a female donor as adverse prognostic factors, with advanced disease having the greatest negative impact.[281] While this analysis dates back to the pre-imatinib era, it still provides some guidance. Little data is available for haploidentical transplants, but one retrospective study found them to be equally effective as matched sibling transplants.[282] There is consensus that HCT should be offered to all patients with progression to AP/BP.[40,283] There is no evidence that TKIs prior to allografting negatively impact the outcome. On the contrary, for unknown reasons, prior imatinib seems to reduce the risk of chronic graft-versus-host disease (GVHD) and possibly relapse.[284–286] A clinical challenge is not to miss the optimal timing for transplant, as HCT in first chronic phase yields far superior results compared to second chronic phase or in AP/BP. For instance, in the CML study IV 3-year overall survival was 91% for patients transplanted in CP after failing imatinib vs. 59% for patients transplanted in AP/BP.[287] The exceptional sensitivity of CML to the graftVersus-leukemia effect provides opportunities to select the transplant regimen based on the aggressiveness of the disease. There is consensus that bone marrow is preferred over peripheral blood stem cells (PBSCs) in patients with CML-CP, where GVHD is of greater concern than disease control.[288] In contrast patients with transformation to AP/BP, even if they have achieved a second chronic phase, may benefit from PBSCs, accepting a higher risk of GVHD. High relapse risk patients should receive a TKI post-transplant. In the absence of clear data it is our practice to treat patients with a TKI for at least one year post HCT, even if they are PCR-undetectable. This approach must be balanced against the toxicity of TKIs in the post-transplant setting, particularly myelosuppression. *BCR-ABL1* mutation analysis at the time of resistance may aid in TKI selection. Given the high median age at the time of diagnosis, many patients will be eligible only for reduced-intensity conditioning regimens. An in-depth discussion of the various conditioning regimens, selection of bone marrow vs. PBSCs, and post-transplant immunosuppression is beyond the scope of this chapter.

APPROACH TO THE NEWLY DIAGNOSED CHRONIC PHASE PATIENT

After completion of staging and risk assessment, the question is how to choose among the four approved TKIs. Several considerations factor into drug selection, not all of which are strictly medical. Thus far (2021), the only trial showing improved overall survival for a second generation TKI compared to imatinib 400 mg daily is the high-dose nilotinib arm (400 mg twice daily) of the ENESTnd study.[263,289,290] However, this dose is not approved as frontline therapy. At the next level, progression free survival was lower for all approved second-generation TKIs compared to standard dose imatinib, although this difference reached significance only for nilotinib. In contrast, all three second-generation TKIs are clearly superior in terms of MMR and DMR, which are achieved sooner and in a larger proportion of patients (see Table 69.5). Across all studies, differences in progression free survival, MMR, and DMR tend to be greatest in Sokal high-risk patients, somewhat less in Sokal intermediate-risk, and small in Sokal low-risk. Unfortunately, the available data is patchy due to the use of the Euro Score in the DASISION trial and inconsistent analyses. Nonetheless, both the ELN and the NCCN guidelines recommend a second-generation TKI for Sokal high- and intermediate-risk patients, noting that imatinib is an acceptable choice.[40,283] An increasingly important consideration is DMR, which is the basis for a trial of TFR. Since the success rate of TFR is very consistent across different populations of CP-CML patients, higher rates of DMR are expected to translate into higher rates of TFR (see also section on "TFR"). An equally important factor is the patient's past medical history and risk factors. Some adverse effects are shared across all or the majority of TKIs approved for first-line therapy, while others are specific to a particular drug (Table 69.6). For instance nilotinib is associated with arterial occlusive events, impaired glucose tolerance, and dyslipidemia. It is contraindicated in patients with a history of diabetes, hypercholesterolemia, or cardiovascular disease. Dasatinib frequently causes pleural effusions, and sometimes pulmonary hypertension, and is contraindicated in patients with pre-existing pulmonary disease. Bosutinib is associated with liver toxicity and renal impairment. Overall second-generation TKIs demonstrated improved tolerability compared to imatinib in phase 3 studies. While imatinib is associated with many low-grade toxicities that can significantly impair quality of life, it has proven to be extremely safe over more than 20 years of clinical use. In contrast,

some toxicities of second-generation TKIs are potentially fatal, which may be one reason why improved progression free survival has not translated into improved overall survival, but studies directly comparing the different second-generation TKIs are unavailable. Additional considerations include co-medications, convenience (once vs. twice daily dosing; food interactions), and costs (financial toxicity). Second-generation TKIs are consistently more expensive than imatinib, and the introduction of generic imatinib has led to an enormous difference in countries such as Canada. In many cases, there are no firm contraindications against any one of the four TKIs, and it can be a matter of trial and error to identify the drug with the optimal tolerability in a given patient. In this complicated space of abundant and yet incomplete data, it is important to define the goals of therapy in an informed discussion with the patient that aims at shared decision making. In young patients, TFR should receive strong consideration as the treatment goal. Women who wish to start a family may want to maximize their chances of achieving DMR and subsequently TFR to avoid the need to interrupt TKI therapy during pregnancy. In older patients with cardiovascular risk, overall survival is the key consideration, and imatinib with its low (or absent) cardiovascular toxicity is the drug of choice. In this context, recent data for dasatinib suggest that a starting dose of 50 mg daily, half the current label dose, produces excellent results.[291] Using this approach, drug interruptions due to toxicity were minimized, which may have compensated for the reduction in daily dose. Similar observations were made for imatinib, where a flexible dosing strategy aimed to minimize protocol-driven dose interruptions seemed to improve efficacy.[291] More research into this strategy is clearly warranted. (See boxes on Cardiovascular Tyrosine Kinase Inhibitor Toxicity, Finding the Best Tyrosine Kinase Inhibitor Dose, and Rapid Tyrosine Kinase Inhibitor Cycling.)

APPROACH TO THE PATIENT WITH TYROSINE KINASE INHIBITOR RESISTANCE

Chronic Phase of Chronic Myeloid Leukemia

Failure to achieve therapeutic milestones or loss of response suggests TKI resistance. As TKI resistance is a consequential diagnosis associated with less favorable outcomes, it is mandatory to exclude other causes. The first call of order is a thorough history to assess drug compliance. Drug level testing, while available in some specialized labs, is not routine practice, and patients have been found to make up for skipped doses during the last few days prior to the

FINDING THE BEST TYROSINE KINASE INHIBITOR DOSE

Most CML patients are on long-term TKI therapy, and managing toxicity is critically important to maintain compliance. Recommended TKI dosing as per package insert is based on early efficacy endpoints that do not reflect the reality of chronic therapy. Dose reduction strategies have received relatively little attention, although a recent study suggests that it is safe and may improve the rate of TFR.[292] This suggests that lower doses of dasatinib, nilotinib, or bosutinib can be considered in patients with good disease control (MMR or better) who experience severe toxicity, but are not candidates for or not comfortable with a trial of TFR. We have found that dasatinib at 20 mg daily can be an effective and very well tolerated maintenance, especially in older patients, and the same holds true for lower doses of bosutinib or nilotinib. It is important to discuss with the patient that relatively little data is available, and that regular PCR monitoring is essential.

CARDIOVASCULAR TYROSINE KINASE INHIBITOR TOXICITY

Arterial occlusive events and other types of cardiovascular (CV) toxicity are of significant concern in patients on TKI therapy, with the notable exception of imatinib. Although incidence is highest with ponatinib and nilotinib, CV risk is also increased with dasatinib and to a lesser extent bosutinib.[293] It is likely that different mechanisms are operational with the different TKIs, although it remains possible that inhibition of ABL1 itself contributes to toxicity. Regardless, there is no uniform preventive strategy other than minimizing CV risk and selecting the most appropriate TKI for a given patient. In our practice we initially determine CV risk using the Framingham score. While patients with low risk (<5%) are eligible in principle for all TKIs, we avoid nilotinib in patients with higher CV risk. Imatinib is strongly considered for patients with high CV risk, and we have a low threshold in obtaining a cardiology consult, particularly if a high-risk agent such as ponatinib is under consideration based on the patient's CML. All patients are followed using a set of practice guidelines tailored to the specific TKI.

Provisional Recommendation for Cardiovascular Monitoring of Patients on Tyrosine Kinase Inhibitors

RAPID TYROSINE KINASE INHIBITOR CYCLING

With the availability of multiple TKIs, it is tempting to switch therapy rather than first making an attempt to manage toxicity to fully exploit the potential of a given TKI. As a result, some patients rapidly cycle through all approved TKIs and are then labelled as pan-TKI intolerant. While pan-TKI intolerance clearly exists, it is rare, and the diagnosis should me made with great caution, given that alternative therapies (IFN-α and SCT) are typically more toxic than TKIs. Perhaps the most important strategy to avoid this scenario is to be realistic and properly manage expectations up front. Every TKI has side effects, and may impair quality of life. On the positive side, for CP-CML patients there is an almost normal life expectancy, an incredible achievement compared to the pre-TKI era. In selected cases of severe or unusual toxicity, drug level testing can provide useful information to inform the use of unusually low doses.[294] It can be challenging to distinguish between TKI toxicity and the many other causes of headaches, fatigue, and other hard to objectively evaluate complaints. Exploring other causes such as stress at the workplace or in the family can reveal surprising results. As everywhere in medicine, taking the time to listen and pick up clues is essential. Lastly non-drug strategies, such as exercise and mediation, should be part of the management to minimize poly-pharmacy. Sometimes it is helpful to emphasize that not every day is perfect, even for perfectly healthy individuals. In other words, that life itself has side effects.

office visit.[295] Possible drug interactions should be reviewed, ideally involving a clinical pharmacologist, especially in patients on multiple co-medications. It is very important to include herbal preparations, supplements, and over-the-counter remedies—for example, St. John's Wort, which can drastically lower imatinib plasma concentrations.[296] It is nearly impossible to accurately predict drug interactions in patients on polypharmacotherapy, and the situation is even more complicated in cases of impaired renal or hepatic function. If non-adherence or drug interactions seem unlikely, a complete resistance workup is indicated, including physical exam, CBC, bone marrow aspirate and biopsy, bone marrow metaphase karyotyping, and *BCR-ABL1* qPCR and mutation screen. Key data gained from this workup are disease phase, *BCR-ABL1* mutation status, and karyotype, including CCA/Ph$^+$.

Patients with resistance to imatinib can be managed with a second-generation TKI as long as they are in chronic phase and do not have the *BCR-ABL1*^{T315I} mutation. The selection of dasatinib, nilotinib, or bosutinib is based on past medical history to minimize side effects and the type of *BCR-ABL1* mutation if present (Table 69.7). Ponatinib is the only option for patients with *BCR-ABL1*^{T315I}. It is good clinical practice to have the patient evaluated or re-evaluated by a transplant center. Analogous to newly diagnosed patients, patients on second-line TKIs must be assessed at regular intervals to determine whether their response meets expectations. One study showed that only 7% of patients who failed to achieve a minor cytogenetic response ($\leq$65% Ph$^+$ metaphases) to dasatinib or nilotinib at 3 months were in MCyR at 12 months, while MCyR at 12 months predicted progression-free and overall survival.[297] Although data are limited, we generally follow the consensus response milestones used for first-line TKI therapy. Patients who fail frontline or second-line second-generation TKI are at high risk, even if still in CP, and have limited drug treatment options. Switching from one second-generation TKI to another produces CCyR rates of only ~20%, and responses are generally not durable.[298] Except in patients where a specific *BCR-ABL1* mutation suggests that another second-generation will be effective, ponatinib is the TKI of choice, with an estimated 5-year overall survival of 73%.[299] Evidently, ponatinib's cardiovascular risk must be taken into account. Additionally, experimental agents and/or allogeneic stem cell transplant must be considered.

Accelerated Phase/Blast Phase Chronic Myeloid Leukemia

Patients who progress to AP/BP on TKI therapy are candidates for HCT, and the purpose of salvage drug therapy is to establish a second chronic phase. Patients with AP-CML are managed with an appropriate TKI, following the same strategy as described for CP-CML. A clinical trial should be strongly considered and is the best option for patients who have failed ponatinib and are ineligible for SCT. Patients with progression to BP-CML may be managed with a combination of TKI and chemotherapy. In patients who still have a TKI option, it is important to weigh the risk of chemotherapy against the potential gain in efficacy, since severe chemotherapy-induced toxicity may delay SCT and increase transplant-related toxicity. Additionally the superiority of TKI/chemotherapy combinations versus TKI alone in AP/BP-CML has never been established in a controlled trial setting. Reduced intensity approaches such as combinations of TKIs with hypomethylating agents in M-BP and vincristine/prednisone in patients with L-BP should be considered, particularly in older patients and those with a reduced performance status.

TREATMENT-FREE REMISSION

The Stop Imatinib Trial (STIM-1) was the first prospective study that systematically evaluated whether TKI discontinuation is feasible.[39] Patients with $MR^{5.0}$ on imatinib for at least 2 years were eligible. Molecular recurrence was defined as any two consecutive positive PCR results or loss of MMR in a single test. At 12 months of follow-up, the projected recurrence free survival was 41%, with the overwhelming majority of recurrences occurring within 6 months of discontinuation, and no recurrence after 21 months. At 67 months, 39% of patients maintained TFR.[300] Patients who experienced recurrence recaptured MMR upon resumption of TKI therapy. Longer TKI exposure and longer duration of DMR were associated with a higher probability of successful TFR, while patients with high Sokal scores were at a higher risk of recurrence. Multiple subsequent TFR studies used modifications to the eligibility and recurrence criteria, but yielded remarkably similar results. TFR rates varied mostly between 40% and 60%, with higher rates observed when loss of MMR was used as a more lenient definition of failure.[301] Several independent studies have identified associations between cellular immune parameters and TFR, including higher NK cells, lower T regulatory cells, and lower numbers of CD86$^+$ plasmacytoid dendritic cells.[302–304] Studies to mechanistically link these immunologic phenomena with TFR have yet to be conducted. In practice, longer duration of TKI exposure and DMR are the most consistent clinical parameters predicting successful TFR.

After the initial TFR studies following imatinib therapy, the same approach was tested in patients with DMR on a second-generation TKI, again with very similar results, although follow-up was shorter compared to imatinib.[305–310] Given the higher rates of DMR in CP-CML patients treated up front with a second-generation TKI, this should translate into higher overall rates of TFR, which argues for starting patients on a second-generation TKI. The risk/benefit assessment of this situation is complex, as any TFR gain with second-generation TKIs must be balanced against the increased risk of serious AEs, such as cardiovascular events on nilotinib.[311,312]

About one-quarter of patients who discontinue TKIs develop a "TKI withdrawal syndrome," consisting primarily of musculoskeletal pain, sometimes accompanied by flushing.[313] Patients with preexisting arthritis appear to be especially susceptible. Over-the-counter anti-inflammatory agents or a short course of steroids are usually effective, but some patients may require opiates or even resumption of TKI therapy. The etiology of the TKI withdrawal syndrome remains enigmatic, but cytokine release, regrowth of mast cells, and reactivation of an underlying, TKI-suppressed inflammatory condition are under consideration. Patients experiencing TKI withdrawal syndrome appear to have a higher likelihood of successful TFR.

The sobering news is that only a minority of newly diagnosed CML patients are likely to enter successful TFR. This is based on the following calculations, which apply to developed countries only. Approximately 10% of patients present with AP/BP and are not considered TFR candidates. Of the remaining 90%, at best 60% will achieve sustained DMR, even if started on a 2G TKI. Of these, at

best 60% (or 32.4% of all newly diagnosed patients) will enter TFR if recurrence is defined as loss of MMR. For the remaining majority, lifelong TKI therapy is required. (See box on Selecting Patients for Treatment-Free Remission.)

FUTURE DIRECTIONS

CP-CML patients treated with TKIs have a life expectancy close to aged-matched controls.[152] In fact the survival of these patients is driven much more by comorbidities than by CML.[315] In practice this means that hematologists treating CML patients need to pay attention to concomitant medical conditions or carefully coordinate care with other specialists, such as cardiologists. The fact that the decades-old goal of CML therapy, a normal life span, has been attained, raises the question whether treatment goals need to change from overall survival to TFR. If TFR is the accepted goal, then using a second-generation TKI up front is justified. Unfortunately second-generation TKIs are sometimes associated with irreversible toxicity, and only one-third of patients will achieve TFR, creating a difficult competing risk scenario. Contrary to expectations, starting patients on a second-generation TKI is not cost-effective, even if the higher TFR rates are taken into account and assuming a relatively high price for generic imatinib.[316] As most CML patients will require lifelong therapy to avoid disease recurrence, developing strategies to increase rates of DMR and successful TFR is paramount. Unfortunately, implementing the clinical trials needed to test the many rational drug combinations

SELECTING PATIENTS FOR TREATMENT-FREE REMISSION

TFR has fairly rapidly moved from anecdote through clinical trials to mainstream practice, including the NCCN guidelines and ELN recommendations.[40,283] Although multiple clinical studies have shown that TFR is safe, observational data from the community are sparse. One observation deserves particular attention. While most tightly controlled and/or industry-sponsored trials showed that most recurrences occur relatively early, with a stable plateau thereafter, there is a slow but continuous attrition of the recurrence free survival curve in the international multi-institutional EuroSKI trial, the largest study conducted thus far.[314] The reasons for this discrepancy are unknown. One possibility is that patients with less deep responses were included. As the EuroSKI trial is a better reflection of the "real world," this suggests that monitoring must continue indefinitely. In a fragmented health care system like the one on the US, with frequent changes of insurance, this can be challenging. On the other hand, given that long-term TKI toxicity remains a concern, a TFR attempt is more than just a consideration, but close to a mandate in well selected patients. By analogy, would one continue antibiotics if there was a 50% chance that the infection had been cleared and re-treatment was practically always effective? In our practice we recommend a TRF trial to every patient who qualifies based on the NCCN consensus guidelines, which include

- Age ≥18 years
- History of good compliance
- CP-CML, no prior AP/BP
- TKI therapy for ≥3 years
- Quantifiable BCR-ABL1 transcript
- Stable DMR for ≥2years
- Access to reliable qPCR testing, with results expressed on the IS
- Monthly testing for month 1–6, 2-monthly for month 7–12, and every 3 months there after
- Prompt resumption of TKI therapy upon loss of MMR

identified in preclinical models has been challenging, and the few studies that performed thus far failed to yield a conclusively positive result (see Table 69.2). Establishing pre-clinical models that more faithfully reflect human CML and simplifying clinical trials will be critical for progress. Another question is whether we have exploited the entire potential of inhibiting BCR-ABL1 in the first place. The abandoned EPIC study of ponatinib 45 mg daily in newly diagnosed patients with CP-CML may provide some insights. Although only 73 patients were evaluable for response at 6 months, the DMR rate was 32% compared to ~5% with nilotinib 300 mg twice daily in the ENESTnd study. Although one cannot exclude that off-target effects of ponatinib have contributed to this high efficacy, these data may suggest that a very potent yet well-tolerated TKI is the first step to maximizing TFR rates.[274] In this context, asciminib, the first clinical allosteric ABL1 TKI, is of considerable interest. Asciminib targets the myristate binding pocket of BCR-ABL1, enforcing an inactive kinase conformation. The drug inhibits BCR-ABL1 at sub-nanomolar concentration, on par with ponatinib and dasatinib.[35,317] A phase 1 study showed considerable clinical activity in patients who failed multiple ATP site TKIs. Toxicity was low, reflecting extremely high selectivity and suggesting that high doses may be tolerated, achieving deep suppression of BCR-ABL1 kinase activity.[318] A subsequent phase 3 study compared asciminib 80 mg daily with bosutinib 500 mg daily in patients with failure to two or more prior TKIs, but without the BCR-ABL1T315I mutation.[319] Asciminib was superior in the primary endpoint, MMR at 6 months (25.5 vs. 13.2%, a 12.2% (95% CI, 2.19–22.30) after adjusting for MCyR status at baseline, leading to FDA approval. Asciminib has further enriched the treatment options for CML. How exactly asciminib will fit into the treatment paradigm in the salvage and ultimately frontline setting will require additional studies.

TKI therapy of CML established the paradigm of molecularly targeted therapy, and lessons continue to be learned from the ongoing history of CML, some of which have reached the broader societal context. CML TKIs are extremely expensive, particularly in the United States, which does not have the political will to put mechanisms in place to prevent excessive health care system exploitation. As a result, the price of imatinib increased in leaps throughout a patent's lifetime, without apparent reason. Even today generic imatinib continues to be many times more expensive than in neighboring countries. While patients may eventually gain access to the TKI most suitable for them through assistance programs, precious time and resources are wasted on bureaucratic processes that are of no societal value. It is my impression that most patients who die from CML in 2020 are the victims of a society that spends more on health care than any other and yet fails to provide equal and easy access to care for its most vulnerable members. For this to improve, more is needed than another TKI.

CHAPTER 70

THE POLYCYTHEMIAS

Marina Kremyanskaya, Vesna Najfeld, John Mascarenhas, and Ronald Hoffman

Under normal conditions, the red blood cell (RBC) mass in humans is tightly controlled and remains relatively constant in a given individual. The numbers of senescent RBCs lost daily are replaced by newly formed ones by a carefully controlled network of growth factors, progenitor and precursor cells. Erythropoiesis can be augmented by a variety of stimuli that increase the delivery of oxygen to tissues. This delicate balance can be disturbed by various pathologic conditions and can result in either reduced numbers of RBCs (anemia) or excessive numbers of RBCs (polycythemia). Hematocrit values over 49% in males and 48% in females are abnormal and require further evaluation to determine if the patient has an absolute increase in their RBC mass and if investigation of its cause should be pursued. The RBC mass is increased if it is greater than 125% above that expected for sex and body mass. The measurement of the RBC mass is a diagnostic study that is now available at a dwindling number of tertiary care centers, making other diagnostic studies pivotal in evaluating patients with elevated hematocrit levels. Polycythemic states can be due to a variety of disorders that can be attributed to several pathophysiologic mechanisms. Determination of the etiology of an individual's polycythemia is a critical step in defining the patient's appropriate prognosis and treatment plan. Primary polycythemias are the result of innate abnormalities involving hematopoietic progenitors and stem cells that lead to constitutive overproduction of RBCs, accompanied by low erythropoietin (EPO) levels. By contrast, secondary polycythemias are the consequence of a number of conditions that lead to increased EPO production, which acts on normal progenitors to overproduce RBCs. In a small number of patients, the cause of erythrocytosis cannot be determined; these patients are classified as having idiopathic erythrocytosis.

ERYTHROPOIESIS

RBC production can be influenced by numerous factors, including nutrients, growth factors, numbers and function of bone marrow (BM) progenitor and precursor cells, and cellular receptors and transcription factors (Chapter 27). EPO is considered to be the physiologic regulator of the terminal phases of erythropoiesis. Alterations in its production are followed by adjustments in the rate of formation of RBCs. In humans, EPO production is controlled by the relative supply of oxygen to the kidneys, the major site of EPO production. In states of severe hypoxia, EPO production can be increased up to 1000-fold. In a healthy person after phlebotomy, EPO production increases, and an inverse logarithmic relationship between hematocrit and EPO production rates exists. Patients with secondary erythrocytosis caused by chronic hypoxia have either normal or increased basal EPO values, but they also have increased values after reduction of the hematocrit to normal levels by phlebotomy. By contrast, EPO excretion is invariably subnormal in patients with polycythemia vera (PV), which demonstrates that this disorder is not a result of excessive EPO production.

ERYTHROPOIETIN, OXYGEN SENSING, AND HYPOXIA-INDUCIBLE FACTOR

Under normal conditions, EPO production is mediated by a reduced oxygen content, termed *hypoxemia*, which leads to decreased oxygen delivery to tissues (Chapter 27). Regulation of oxygen homeostasis is critical to survival. In humans, oxygen sensing occurs at many levels, leading to both acute and chronic adaptation. The acute reduction of the availability of oxygen leads to the initiation of a cascade of adaptive events that sets in place compensatory events to correct the lack of oxygen supply.[1] Low oxygen levels, or hypoxia (60 mm Hg), in humans causes oxygen-sensing chemosensory cells to undergo rapid membrane depolarization within seconds, leading to the production of action potentials, influx of calcium ions, and release of the neurotransmitters that result in stimulation of the brain stem that controls the respiratory and cardiovascular systems. These chemosensory cells are found within the glomus cells of the carotid body located at the bifurcation of the internal and external carotid arteries. The released neurotransmitters activate the nerve endings of the carotid body sensory nerve to convey to the CNS signals that command ventilation to fight hypoxia, resulting in an increase of the ventilation rate and restoration of normal oxygen tension to vital organs. In addition, there are changes in blood pressure and heart rate to maximize oxygen delivery. The carotid body is the organ with the greatest blood flow within the body. Activation of the carotid body results in the sensation of breathlessness experienced by individuals at high altitudes. During chronic hypoxia when the carotid body is permanently active, there is marked enlargement of the carotid body because of an increase in capillaries and a marked reduction in the mean distance from the capillaries to the edge of the chemoreceptor cells.

In response to chronic hypoxia, multiple compensatory mechanisms come into play over several days within the kidneys, the major site of EPO production. Lack of oxygen activates the cellular signaling pathway of the hypoxia-inducible transcription factors (HIF) that has three isoforms, hypoxia-inducible factor (HIF)-1, HIF-2, HIF-3, regulating expression of several thousand genes. Within the kidney, specialized interstitial cells are the source of EPO. These cells employ the HIF pathway, a pathway that is otherwise present in essentially all cells of the body, to regulate EPO production in an oxygen-sensitive manner. Hypoxic stimulation results in production of HIF-1/HIF-2, the major factors responsible for transcriptional activation of the *EPO* gene.[2] The HIF transcriptional system is a master regulator of the hypoxic response controlling a large number of genes in multiple cell types. HIF-1 is a heterodimeric protein consisting of HIF-1/HIF-2α and HIF-1β, which is required for normal development of the heart, blood vessels, and blood cells. As the key mediator of cellular oxygen maintenance, HIF-1 facilitates body oxygen delivery and responses to oxygen deprivation by regulating the expression of gene products that are involved in cellular energy metabolism and glucose transport, angiogenesis, erythropoiesis and iron metabolism, pH regulation, apoptosis, cell proliferation, and cell–cell and cell–matrix interactions. Classic HIF target genes include phosphoglycerate kinase, glucose transporter-1, vascular endothelial growth factor (VEGF), and EPO. The HIF proteins are members of the Per–ARNT–Sim family of heterodimeric basic helix–loop–helix transcription factors (Fig. 70.1).

In contrast to the constitutively expressed, HIF-1β subunits, HIF-1α is an oxygen-labile protein that becomes stabilized in response to hypoxia. HIF-1α mRNA and protein levels are induced by hypoxia, and HIF-1α protein levels decay rapidly with return to normoxia. The posttranslational regulation of HIF-1α protein accounts for the majority of the regulation of this gene. Normoxia-induced, ubiquitin-mediated degradation of the HIF-1α protein is the major regulator of HIF-1α levels, thereby reducing the stimulus for additional EPO production. The targeting and subsequent polyubiquitination of HIF-1α require the von Hippel-Lindau (VHL) protein, oxygen, and three different iron-requiring proline hydroxylase (PHD) enzymes (see Fig. 70.1). The PHD proteins exist in three isoforms, PHD1, PHD2, and PHD3. HIF-1α is hydroxylated by all three isoforms but primarily by PHD2. The prolyl hydroxylation of HIF-1α is necessary for the binding of HIF-1α to VHL, which is the substrate-recognition subunit of an E3 ubiquitin-protein ligase. Different parts of the HIF-1α chains have different functions. The N-terminus part of HIF-1α is involved in DNA binding and dimerization, and the C-terminus portion has regulatory functions. One domain at the C-terminus influences transcriptional activity without affecting HIF-1α protein levels, and the other region, termed the oxygen-dependent degradation domain (ODD), affects protein abundance. The VHL protein physically interacts with the ODD of HIF-1α, targeting it for ubiquitination and destruction by the proteasome. Iron-chelating drugs can also block the interaction of HIF-1α with the VHL protein, suggesting a role for iron in the degradation of HIF-1α.

Under normoxic conditions, hydroxylation of HIF-1α/HIF-2α is essential for HIF proteolytic degradation by promoting interaction with the VHL tumor-suppressor protein through hydrogen bonding to the hydroxy proline-binding pocket in the VHL-β domain. As oxygen levels decrease, hydroxylation of HIF decreases, and HIF-1α/HIF-2α then no longer binds VHL. As a result, HIF-1α/HIF-2α become stabilized, dimerize with HIF-1β, and activate transcription of target genes. The activity of PHDs depends on the availability of molecular oxygen, which qualifies these enzymes as oxygen sensors. In addition, these dioxygenases require 2-oxyglutarate which acts as a cosubstrate with vitamin C to keep nonheme iron in the ferrous state. Although PHD-2 appears to be the hydroxylase that is essential for HIF-1α/HIF-2α degradation under normoxic conditions, PHD-3 is important for hydroxylation of HIF-1α/ HIF-2α during reoxygenation. Different effects of individual PHDs on HIF-1α and HIF-2α hydroxylation indicate that the stability of individual HIF-1α subunits and their target gene expression might be affected by tissue- and cell-type differences in PHD expression and activity levels. The activity of PHDs can be modulated by mitochondrial reactive oxygen species, implicating mitochondria in oxygen sensing. HIF-2α under hypoxic conditions dimerizes with HIF-1β and activates the transcription of a set of target genes that overlap with the target genes regulated by HIF-1α/HIF-1β heterodimers. HIF-1α is expressed by all nucleated cells, but HIF-2α is expressed by specific cell types, including vascular endothelial cells, renal interstitial cells, hepatocytes, cardiomyocytes, and astrocytes. HIF-2α appears to play a critical role in regulating EPO production in adult mammals[2] and HIF-1α is important during yolk sac erythropoiesis. HIF-1 also controls the absorption and delivery of iron to the BM by repressing of hepcidin and activation of genes encoding transferrin and the transferrin receptor.

HIF3α is another HIF protein which is an oxygen-dependent transcription factor which activates a distinct transcriptional response to hypoxia. Mammalian *HIF-3* genes use different promoters, different transcription initiation sites, and alternative splicing to transcribe a large number of mRNA variants. While some short HIF-3α variants act as dominant-negative regulators of HIF-1/2 actions, other HIF-3 variants can inhibit HIF-1/2 actions by competing for the common HIF-β. It is thought that HIF3 acts as a negative regulator of HIF-1 and HIF-2. Similar to HIF1 and HIF2, *PHD1*, *PHD2*, *PHD3*, and *VHL* also cause HIF-3 protein degradation. Further studies of HIF-3α variants will provide new and important insights into HIF biology.[3]

VHL syndrome is a hereditary cancer syndrome that is associated with exaggerated responses to hypoxia caused by posttranslational abnormalities in HIF. VHL syndrome is characterized by a propensity for developing clear-cell renal carcinomas, retinal

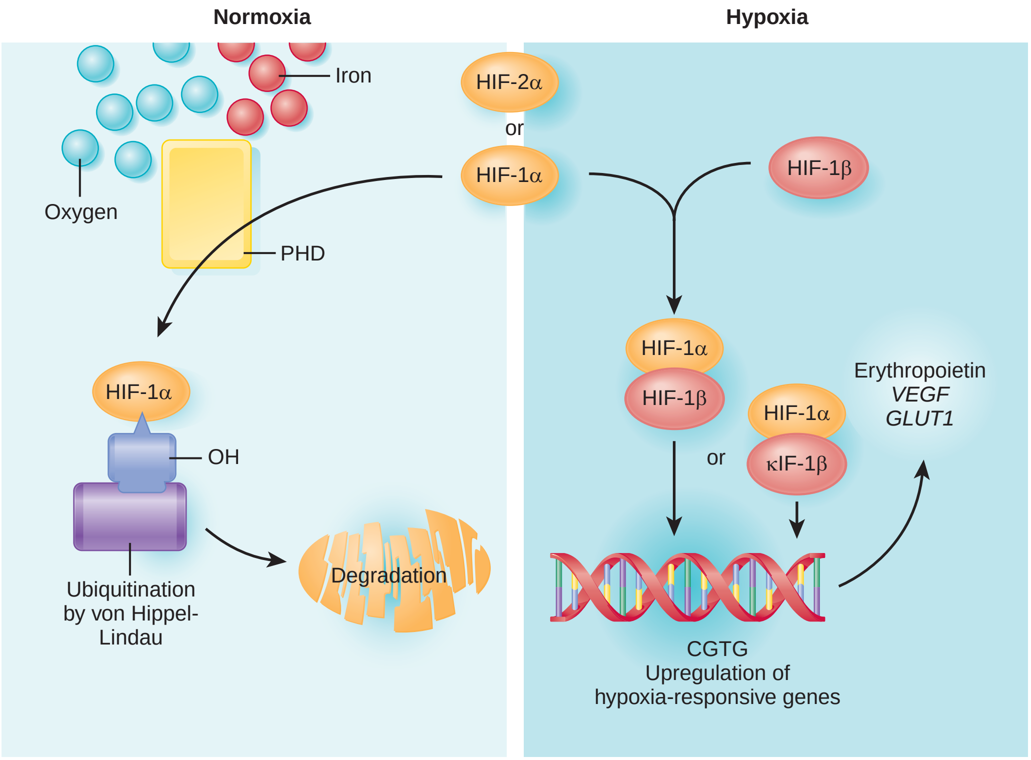

Figure 70.1 SCHEMATIC REPRESENTATION OF THE RELATIONSHIP BETWEEN HYPOXIA SENSING AND ERYTHROPOIETIN PRODUCTION. *GLUT*, Glucose transporter 1; *HIF*, hypoxia-inducible factor; *PHD*, proline hydroxylase; *VEGF*, vascular endothelial growth factor.

hemangioblastomas, cerebellar and spinal hemangiomas, pancreatic and renal cysts, islet cell tumors of the pancreas, and pheochromocytomas.[4] The tumors result from somatic mutations that cause a loss of heterozygosity (LOH) of the *VHL* gene. VHL inactivation leads to aberrant stabilization and accumulation of HIF-2α, which drives tumor cell growth. VHL disease affects approximately 1 in 35,000 individuals and is transmitted in an autosomal dominant manner. Individuals with VHL disease carry one wild-type (WT) *VHL* allele and one inactivated *VHL* allele. This inactivation can occur by somatic mutation or hypermethylation. Tumor or cyst development is linked to somatic inactivation or loss of the remaining WT *VHL* allele. Approximately 20% to 37% of VHL patients have large or partial germ-line deletions, 23% to 27% have nonsense or frame-shift mutations, and 30% to 35% have missense mutations. More than 150 different *VHL* mutations linked to VHL disease have been reported. The tumors linked to *VHL* inactivation are often highly vascular and can produce angiogenic factors such as VEGF. In addition, renal cell carcinoma, cerebellar hemangioblastomas, and pheochromocytomas have been associated with paraneoplastic erythrocytosis caused by overproduction of EPO. Overproduction of HIF-inducible mRNAs is the hallmark of VHL protein defective cells. Genotype–phenotype correlates in VHL disease suggest that VHL has functions independent of HIF regulation that might play a role in tumor formation. VHL protein has other binding partners, including atypical protein kinase C and a family of deubiquitinating enzymes called VHL-interacting deubiquitinating enzymes 1 and 2. In addition, VHL has been involved in numerous cellular processes, including regulation of extracellular matrix, cytoskeleton stability, cell cycle control, and differentiation. VHL disease is not associated with erythrocytosis.

This growing understanding of intracellular responses to hypoxia has led to the development of new therapeutic strategies for treating solid tumors which was recognized in 2019 by the Nobel Prize in Physiology and Medicine being awarded to William G. Kaelin, Jr., Sir Peter J. Ratcliffe, and Gregg L. Semenza. Many cancers contain areas of intra-tumoral hypoxia, and primary tumors with low oxygen levels are associated with an increased risk of metastasis and patient mortality. Increased HIF-1 levels are associated with increased risk of mortality in patients with many human cancers, including those involving the bladder, brain, breast, colon, esophagus, head/neck/oropharynx, liver, lung, pancreas, skin, stomach, and uterus, as well as in acute lymphocytic and myeloid leukemia. By contrast, in colon carcinoma and clear cell renal cell carcinoma HIF-2 overexpression is associated with disease progression and mortality.[5]

The possibility that HIF family member inhibitor therapy might be used to treat solid tumors was hypothesized by many and recently confirmed by the FDA approving belzutifan. Belzutifan is an oral HIF-2α inhibitor used to treat adults with VHL syndrome who require therapy for associated renal cell carcinoma, central nervous system tumors, hemangioblastomas, or pancreatic neuroendocrine tumors not requiring immediate surgery. In a phase I study of patients with clear cell renal cell carcinoma reduced EPO levels were observed at all doses administered. The confirmed objective response rate was 25% (all partial responses), and the median progression-free survival was 14.5 months. The most common grade $\geq$ 3 adverse events were anemia (27%) and hypoxia (16%). Belzutifan was well tolerated and demonstrated preliminary antitumor activity in heavily pre-treated patients, suggesting that HIF-2 α inhibition might offer an effective treatment for clear cell renal cell carcinoma.[6]

THE ERYTHROPOIETIN RECEPTOR

Interaction of EPO with the EPO receptor (EPOR) present on the erythroid progenitor and precursor cells leads to its homodimerization, resulting in (1) stimulation of cell division, (2) differentiation by induction of erythroid-specific gene expression, and (3) prevention of erythroid progenitor and precursor cell apoptosis. EPOR is a member of the type I cytokine receptor superfamily. Signal transduction through the receptor is initiated by ligand binding, which induces dimerization of EPOR monomers. The predominant signaling cascade activated by EPOR and other cytokine receptors is the Janus-activated kinase (JAK)/signal transducer and activator of transcription (STAT) pathway. JAK tyrosine kinases are constitutively associated with the membrane proximal regions of cytokine receptor cytoplasmic domains and are activated by receptor dimerization. The EPOR associates predominantly with JAK2. JAK2 binds to the EPOR in the endoplasmic reticulum and acts as a chaperone protein transporting the EPOR to the plasma membrane. Immediately after EPO binding, JAK2 phosphorylates itself and the EPOR on multiple tyrosine residues in its cytoplasmic domain, thus creating a platform for the recruitment and activation of multiple key signaling regulators. One such protein is STAT5. JAK2–STAT5 signaling plays an essential role in EPO/EPOR-mediated regulation of erythropoiesis. Consistent with their essential roles in erythropoiesis, EPO-, EPOR-, and JAK2-deficient mice die embryonically from severe anemia.

The C-terminal cytoplasmic portion of the EPOR also possesses a negative regulatory domain. Hematopoietic cell phosphatase (HCP; also known as *SHP-1* or *PTP N6*) interacts with this portion of the EPOR and downregulates signal transduction by promoting dephosphorylation (Fig. 70.2). Inactivation of the HCP-binding site leads to prolonged phosphorylation of JAK2–STAT5. Another negative regulator of erythropoiesis, suppressor of cytokine signaling-3 (SOCS-3), binds to the cytoplasmic portion of the EPOR and suppresses EPO-dependent JAK2–STAT5 signaling. Thus, deletion of the distal C-terminal cytoplasmic portion of the EPOR abolishes negative regulatory elements and results in increased proliferation of erythroid progenitor cells. Mutations in the *EPOR* gene have been observed in some patients with primary familial and congenital polycythemia (PFCP) and are occasionally found in erythroleukemia (see Fig. 70.2). Such secondary growth factors as insulin-like growth factor-1 (IGF-1) and the components of the renin–angiotensin system (RAS) may also influence the production of RBCs.

THE RENIN–ANGIOTENSIN SYSTEM AND HEMATOPOIESIS

The RAS regulates fluid and electrolyte homeostasis and blood pressure, and has been hypothesized to also play a role in the regulation of erythropoiesis. The primary function of angiotensin during development is the regulation of tissue growth and differentiation. Angiotensin II (Ang II) is a ligand for two distinct receptors, type 1 and type 2 (AT1 and AT2). AT1 appears to play a major role in the regulation of cell proliferation.[7]

The RAS was first postulated to influence erythropoiesis in the 1980s after the use of angiotensin-converting enzyme (ACE) inhibitors to treat hypertension was shown to result in anemia. In animals, increased blood levels of renin (a major regulator of Ang II synthesis) were found to result in elevated serum EPO levels and erythrocytosis. In humans, the infusion of Ang II in healthy volunteers increased serum EPO levels by 35% or higher via activation of the Ang II type I receptor, and ACE inhibitors significantly decrease plasma EPO levels by as much as 20% to 30%. The pathway underlying Ang II-driven EPO secretion is unknown. However, some investigators have suggested that Ang II modulates renal EPO production through changes in renal perfusion and sodium reabsorption. This hypothesis is based on the presumption that reduced oxygen pressure in the kidneys triggers HIF-1α/HIF-2α to induce release of EPO. Ang II also directly stimulates proliferation of hematopoietic progenitors in vitro, and inhibition of this effect with ACE inhibitors induces apoptosis of erythroid progenitors in renal transplantation patients. ACE-1 knockout mice develop a normocytic anemia that can be reversed by infusion

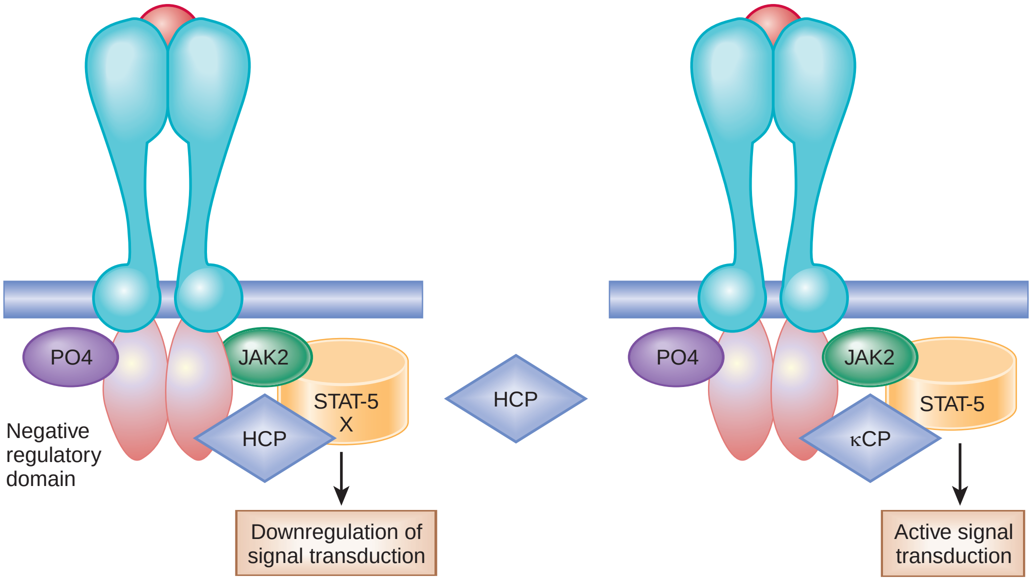

Figure 70.2 SCHEMATIC REPRESENTATION OF THE ERYTHROPOIETIN RECEPTOR AND THE DEFECT IN THE RECEPTOR UNDERLYING PRIMARY FAMILIAL AND CONGENITAL POLYCYTHEMIA. *HCP*, Hematopoietic cell phosphatase; *JAK*, Janus kinase; *STAT*, signal transducer and activator of transcription.

of Ang II. ACE-related anemia is most pronounced in patients with renal insufficiency or end-stage renal disease and in patients who have received a renal allograft. The pathogenesis of this anemia is not clear, but reduced levels of circulating EPO are not solely responsible, suggesting that there might be other contributing factors. The AT1 receptor is present on erythroid progenitors, and its ligand, Ang II, augments EPO stimulation of erythropoiesis. The involvement of JAK2 kinase in Ang II signaling suggests that this signal transduction pathway mediated by EPO and Ang II might overlap. Postrenal transplant erythrocytosis likely can be accounted for by activation of the RAS.

DEFINITION AND CLASSIFICATION OF POLYCYTHEMIA

The term *polycythemia* is a literal translation from Greek, meaning "too many cells in the blood," and refers to an increase in the RBC mass; it is frequently used interchangeably with the term *erythrocytosis*. Polycythemia may be due to a myriad of causes (Table 70.1). The polycythemias can be classified as relative and absolute. Relative polycythemia is a disorder in which the patient characteristically has a modest elevation of the hematocrit level without an elevated RBC mass but rather because of contraction of the plasma volume. The absolute polycythemias are accompanied by an actual increase in the circulating RBC mass. Polycythemias can also be classified according to the responsiveness of their erythroid progenitor cells to growth factors or the circulating levels of such growth factors. Primary polycythemias are characterized by increased sensitivity of the erythroid progenitors to regulatory growth factors as a result of acquired somatic or inherited germ-line mutations expressed by hematopoietic progenitor cells (HPCs). In contrast, secondary polycythemias are characterized by an increase in regulatory growth factors, primarily EPO, and normal responsiveness of their erythroid progenitors to these growth factors. These conditions can usually be distinguished by in vitro assays of erythroid progenitor cells, quantitation of serum EPO levels, and detection of somatic *JAK2* mutations. In a small number of patients, the cause of erythrocytosis cannot be determined; these patients are classified as having idiopathic erythrocytosis.

RELATIVE POLYCYTHEMIA

Individuals with a modestly increased venous hematocrit level that is not accompanied by an increased RBC mass are frequently thought to be polycythemic by imprecise yet widely accepted medical practice. Frequently, these individuals are thought to be polycythemic owing to the lack of appreciation by a clinician of what constitutes the upper limit of normal values for a hematocrit (49% in males and 48% in females). Such individuals frequently prove not to have an absolute polycythemia as defined by an actual increase in the measured RBC mass. *Relative* or *spurious polycythemia* is a term used to describe an elevation of the hematocrit level either caused by an acute transient state of hemoconcentration associated with intravascular fluid depletion or a chronic sustained relative polycythemia caused by contraction of the plasma volume (see Table 70.1).

Transient polycythemias may be a result of acute depletion of the plasma volume from a variety of disorders, including protracted vomiting or diarrhea, plasma loss from external burns, sudden cold exposure or protracted exercise, insensible fluid loss from fever, sepsis, diabetic ketoacidosis, or acute ethanol intoxication. These elevations of hematocrit can be easily corrected by appropriate replacement of intravascular fluids.

Gaisböck syndrome, first described in 1905, is a condition observed mainly in obese, hypertensive, middle-aged, and male smokers. Alcohol, diuretics, obesity, hypoxia, psychologic stress, and excess catecholamine secretion have been identified as possible causes of relative polycythemia. Such individuals can have a chronic modest-to-moderate elevation of the hematocrit level associated with a normal RBC mass and low plasma volume, which has been attributed to reduced venous compliance, or they can have a high normal RBC mass with either a normal or slightly decreased plasma volume. The primary significance of the identification of a patient with relative polycythemia is the recognition of the increased risk of developing thrombotic vascular events likely caused by excessive smoking, hypertension, and obesity associated with this disease. Treatment is generally directed at correction of the patient's underlying cardiovascular risk factors.

It is also important to emphasize that overfilling of blood collection vacuum tubes can result in pseudopolycythemia, pseudothrombocytopenia, and pseudoleukopenia as a result of inadequate sample mixing. Careful attention to such a seemingly trivial detail can help avoid expensive, unnecessary diagnostic workups.

TABLE 70.1 Differential Diagnosis of the Polycythemias

Relative or Spurious Polycythemia

1. Decreased plasma volume—reduced fluid intake, marked loss of body fluids (diaphoresis, vomiting, diarrhea, “third spacing”)
2. Gaisböck syndrome
3. Overfilling of blood in collection vacuum tubes

Absolute Polycythemia

1. Secondary polycythemia
    - A. Acquired
        - Hypoxia
            - Pulmonary disease
            - Cyanotic congenital heart disease
            - Hypoventilation syndromes: sleep apnea, Pickwickian syndrome
            - High altitude
            - Smokers’ polycythemia, hookah polycythemia, carbon monoxide intoxication caused by industrial exposure
        - Postrenal transplantation erythrocytosis
        - Aberrant erythropoietin production
            - Tumors: renal cell carcinoma, Wilms tumor, hepatic carcinoma, uterine leiomyomata, virilizing ovarian tumors, vascular cerebellar tumors
            - Miscellaneous renal and hepatic disorders: solitary renal cysts, polycystic kidney disease, renal artery stenosis hydronephrosis, viral hepatitis
        - Endocrine disorders: Cushing syndrome, primary aldosteronism
        - Androgen use
        - Erythropoietin use
    - B. Congenital polycythemias
        - Abnormal high-affinity hemoglobin variants
        - Bisphosphoglycerate deficiency
        - Congenital methemoglobinemia
        - Chuvash polycythemia (von Hippel-Lindau mutations)
        - Prolyl hydroxylase mutations
        - Hypoxia-inducible factor gene mutations
2. Primary polycythemias
    - Primary congenital and familial polycythemia
    - Polycythemia vera

ABSOLUTE POLYCYTHEMIAS

Primary Familial and Congenital Polycythemia

This is an autosomal dominant disorder. Although PFCP is uncommon, it is more prevalent than polycythemia caused by high-oxygen–affinity hemoglobin mutants or a 2,3-biphosphoglycerate (2,3-BPG) deficiency. Unlike patients with PV, patients with PFCP lack splenomegaly and do not progress to acute leukemia. It is not unusual for these patients to present with headaches, dizziness, epistaxis, and exertional dyspnea that resolve with normalization of the hematocrit level.[8] An increased incidence of cardiovascular events and premature morbidity and mortality has been reported in some affected members, but many appear to have a benign clinical course. Although clinical symptoms are relieved by phlebotomy, the increased risk of cardiovascular morbidity is not corrected by maintaining a normal hematocrit. Characteristic laboratory findings are (1) an increased hematocrit and RBC mass without an increased leukocyte or platelet count, (2) an absence of an activating mutation of *JAK2*, (3) a normal hemoglobin–oxygen dissociation curve, (4) low serum EPO levels, and (5) in vitro hypersensitivity of erythroid progenitors to EPO. Even though PFCP is present at birth, many affected patients are incidentally diagnosed later in life after the performance of routine blood counts or when evaluated in the context of multiple family members having polycythemia. It is of interest that one individual so affected was an accomplished cross-country skier who had won medals at the Olympic Games. Numerous mutations of the EPOR associated with PFCP have been described, leading to a loss in the negative regulatory domain of the EPOR.

The physiologic basis for EPO-mediated activation of erythropoiesis is as follows: EPO activates its receptor by conformational changes of its dimers, leading to initiation of an erythroid-specific cascade of events. The first signal is initiated by the binding of a tyrosine kinase to the EPOR and its phosphorylation and activation of a transcription factor, STAT5, which regulates erythroid-specific genes. This “on” signal is negated by dephosphorylation of the EPOR by HCP, that is, the “off” signal. Truncation of the EPOR leads to a loss in the negative regulatory domain of the EPOR, a binding site for HCP, leading to a gain-of-function mutation of the EPOR (see Fig. 70.2). In addition, the negative regulation of erythropoiesis by SOCS-3, cytokine-inducible SH2 domain containing protein (CIS), and Src homology region 2 domain-containing phosphatase-1 (SHP-1) is presumed to contribute to the underlying cause of PFCP.

Alternative explanations for the increased sensitivity of erythroid progenitors to EPO of patients with PFCP have been proposed. EPOR downregulation provides another mechanism by which EPO desensitization can occur. EPOR downregulation is a complex process that involves EPOR-induced internalization or ubiquitination and degradation by proteasomes. EPO-induced receptor internalization is an efficient means of rapidly reducing EPO responsiveness. This process is mediated by binding of the EPOR to the p85 subunit of phosphatidylinositol 3-kinase (PI3K) but does not involve its kinase activity as the PI3K inhibitor wortmannin does not impair EPOR internalization. All of the truncated mutants associated with PFCP are associated with failure to internalize the EPOR, contributing to prolonged signaling through the EPOR. The EPOR degradation process removes all of the phosphorylated tyrosine residues in the intracellular domain of the receptor, thereby preventing further signal transduction. The remaining part of the EPO–EPOR complex is then internalized and degraded by lysosomes. The E3 ligase B-transducin repeat containing protein-1 (B-Trcp-1) is responsible for EPOR ubiquitination and degradation. Mutations in *B-Trcp-1* abolish EPOR ubiquitination and degradation, making cells expressing the EPORs hypersensitive to EPO. Each of the *PFCP* mutations involving the EPOR results in loss of the binding site for B-Trcp-1. These findings suggest that the EPO hypersensitivity in PFCP might not be attributable to a failure to recruit negative regulators such as phosphatases to inactivate JAK2, or that these mutant receptors are defective in EPO-induced receptor downregulation.

The effect of a truncated EPOR is not always predictable. Some patients who inherit an EPOR mutation are not polycythemic. This observation suggests that undefined environmental or genetic factors may mask the development of polycythemia. Also, the heterogeneity of the polycythemic phenotype observed in a PFCP animal model appears to be strain dependent. This indicates that gene modifiers or epigenetic factors may mask the development of the full PFCP phenotype. Four different rearrangements of the EPOR have been observed in Philadelphia chromosome-like (Ph-like) acute lymphoblastic leukemia (ALL) B cells (Chapters 66 and 68). Normal B cells do not express the EPOR, but the EPOR has been described in ETV6-RUNX1–positive ALL blast cells. These rearrangements are different from those observed in PFCP but result in truncation of the cytoplasmic tail of the EPOR at residues similar to those mutated in PFCP, with preservation of the proximal tyrosine essential for receptor activation and loss of distal regulatory residues. This leads to dysregulated EPOR expression, hypersensitivity to EPO stimulation, and heightened JAK–STAT activation. Expression of truncated EPOR in murine B-cell progenitors leads to the development of ALL in vivo (see Chapters 66 and 68). Several observations suggest that the EPOR mutations in human leukemic cells in Ph-like ALL are driver mutations that are acquired during early stages of leukemogenesis and therefore JAK inhibitor therapy can be used in combination with current ALL treatment strategies to treat patients with this type of leukemia.

SECONDARY POLYCYTHEMIAS

Secondary polycythemias can be either congenital or acquired (see Table 70.1). Conditions leading to hypoxia, such as high altitude, cyanotic heart disease, obstructive sleep apnea or chronic lung disease, may result in physiologic polycythemia mediated by increased levels of EPO. There are marked variations in EPO levels and subsequent erythroid responses in the face of chronic hypoxia, suggesting that some of these factors may be genetically determined. The same degree of renal tissue hypoxia may induce substantially different levels of EPO production in response to high altitude. It is likely that these individual variations are a function of genetic differences in hypoxia sensing and the hypoxia response pathways. For purposes of simplicity and clinical diagnostic usefulness, the secondary polycythemic disorders are divided into those that are acquired and those that are congenital. It should be kept in mind that this division, although useful for purposes of differential diagnosis, is artificial. Patients with inherited germ-line mutations, for instance, can develop an EPO-secreting pheochromocytoma or renal cell cancer, and a patient with PV can smoke and have chronic obstructive pulmonary disease (COPD). In other instances, polycythemia caused by a germ-line mutation can be masked by an acquired environmental factor or another gene-modifying mutation.

Acquired Secondary Polycythemias

Polycythemias of Cyanotic Heart Disease and Pulmonary Disease

Patients with cyanotic heart disease and pulmonary disease frequently have arterial hypoxemia, leading to increased production of EPO and polycythemia. Excessive EPO production occurs when the PaO_2 is sustained below 67 mmHg as a result of severely impaired pulmonary mechanics. Because patients with severe pulmonary disease and secondary erythrocytosis frequently have elevated plasma volumes, the degree of elevation of the hematocrit level may be modest. Hematocrit levels as high as 65% or rarely 75% have, however, been reported. Moderate elevations of hematocrit have been estimated to occur in 20% of patients with COPD. Polycythemia in this setting can contribute to pulmonary hypertension, pulmonary endothelial cell dysfunction, reduced cerebral blood flow, hyperuricemia, gout, and an increased risk of venous thromboembolic disease.

Why some patients with pulmonary disease and congenital heart disease develop polycythemia but others do not remains unclear. Increased oxygen-carrying capacity may improve oxygen delivery; however, it is not obvious at what hematocrit level the resultant elevation in blood viscosity impairs blood flow to the tissues, leading to a reduction in oxygen uptake. In addition, oxygen uptake to the tissues is markedly influenced by whole blood volume. Thus, whereas the optimal hematocrit level for oxygen delivery is about 45% in normovolemic subjects, it rises to over 60% in hypervolemic states, likely as a result of engorgement of the vascular bed and a decrease in peripheral resistance. Furthermore, chronic exposure to hypoxia leads to respiratory alkalosis that in turn promotes the synthesis of 2,3-BPG, facilitating increased oxygen delivery to tissues.

The practical relevance of an elevated hematocrit level in this clinical situation is whether and at what level it is harmful or beneficial. An extremely elevated hematocrit level may be detrimental to optimal oxygen delivery. Extreme but not moderate polycythemia caused by chronic hypoxia may affect systemic vascular function by altering blood viscosity, vessel wall shear stress, reduced endothelial cell–derived nitric oxide release, and increasing the secretion of endothelin. Although it is widely accepted that polycythemic pediatric patients with cyanotic heart disease are at an increased risk for developing cerebrovascular accidents, the literature provides conflicting data as relates to the prevalence of such events among adults. A 10% to 13.6% prevalence of stroke and transient ischemic attacks (TIAs) has been reported in a cohort of adult patients with cyanotic heart disease, but others have claimed that such events are rare. Iron deficiency occurs in more than 30% because of the total depletion of iron stores to support erythropoiesis. Microcytic RBCs are, however, rarely found, and despite the iron deficiency, these patients frequently have normal mean corpuscular volumes and high mean corpuscular hemoglobin concentrations, which might maximize the amount of hemoglobin within an individual RBC, thereby maximizing oxygen delivery. In the past, compensatory erythrocytosis was thought to lead to an increased plasma viscosity, leading to a compromised microcirculation, resulting in symptoms such as headache, sluggish mentation, dizziness, blurry vision, muscle weakness, or paresthesias. In reality, such symptoms are rare in patients with chronic compensated secondary erythrocytosis, and the secondary erythrocytosis is viewed as a physiologically desirable response to chronic hypoxia. The symptoms delineated above are likely attributable to decreased tissue oxygen delivery rather than hyperviscosity.

The treatment of hyperviscosity secondary to erythrocytosis in cyanotic heart disease with prophylactic phlebotomy is rarely used. In fact, phlebotomy has been reported to have harmful rather than beneficial effects in adults with cyanotic congenital heart disease. Because almost one-third of these patients are iron deficient even though their RBC indices do not reflect this, routine assessment of the patient's iron status is suggested with gradual supplementation with sufficient iron to attain appropriate compensatory levels of erythropoiesis but avoiding excessive sudden increases in the degree of erythrocytosis. The present evidence indicates that prophylactic phlebotomy promotes the development of iron deficiency, decreases exercise tolerance, and increases the number of cerebrovascular events. Currently, experts in this field recommend that phlebotomy should be restricted to individuals with symptoms with extreme erythrocytosis (hematocrit >65%) and preoperatively to improve hemostasis. Clinical data to justify these recommendations are lacking. Phlebotomy should be followed by the infusion of an equal volume of fluids to maintain intravascular volume and blood flow, as well as to provide a dilutional effect to reduce the hematocrit level. Hydroxyurea (HU) therapy has been used occasionally to reduce erythropoiesis in this situation to reduce the need for phlebotomy, but little evidence exists for this approach. The superiority of HU therapy versus phlebotomy therapy has not been documented. HU might act not only by suppressing RBC production but also by promoting macrocytic RBC formation, thereby increasing RBC deformability and decreasing RBC adhesiveness.

Chronic oxygen therapy in patients with severe COPD has resulted in relief of hypoxia and a modest reduction in hematocrit levels. Pharmacologic interventions, including theophylline, inhaled nitric oxide, sildenafil, or antagonism of the renin–angiotensin pathway with losartan, may also reduce the degree of pulmonary hypertension or secondary erythrocytosis. In a retrospective study, hematocrit levels were found to be significantly lower in 50 COPD patients with erythrocytosis receiving theophylline as compared to levels in the 61 patients not receiving theophylline. Since the levels of oxygen saturation were similar in both groups, the normal hematocrit levels in the theophylline treated group could not be explained by improved oxygen availability. Serum EPO levels, however, declined in 70% of theophylline treated patients. Theophylline has previously been shown to reduce the production of EPO in both normal subjects and patients with erythrocytosis after renal transplantation and is likely acting in a similar fashion to reduce the degree of erythrocytosis in COPD patients.[9]

Obstructive Sleep Apnea–Induced Polycythemia

Obstructive sleep apnea syndrome is characterized by repetitive episodes of partial or complete obstruction of airflow during sleep. Common symptoms include loud snoring and breathing pauses observed by a bed partner, feelings of nonrefreshing sleep, and excess daytime sleeping. Although the evidence is largely anecdotal and somewhat controversial, secondary polycythemia is a recognized complication of long-standing sleep apnea. The factor that seems to have the strongest prediction for polycythemia is nocturnal mean oxygen saturation.[10] On the other hand, most studies demonstrate that the apnea-hypopnea index does not reliably associate with polycythemia except in severe cases. The mechanism by which sleep apnea can cause polycythemia is unclear. Differences in EPO levels between normoxic and hypoxemic patients referred for suspected sleep apnea have not been documented. Obstructive sleep apnea is also associated with an increased risk of developing cardiovascular diseases, including systemic hypertension, pulmonary hypertension, cardiac arrhythmias, atherosclerosis, ischemic heart disease, and stroke. Intermittent hypoxia is thought to be a major cause of cardiovascular complications. These patients undergo repeated episodes of hypoxia and normoxia. The hypoxia leads to ischemia, and the reoxygenation causes a sudden increase of oxygen. This reoxygenation phase results in the production of reactive oxygen species and the promotion of oxidative stress, leading to an inflammatory response and the development of vascular complications. Nguyen and Holly analyzed 1604 consecutive veterans undergoing sleep evaluations for suspected obstructive sleep apnea to identify the incidence and causes of erythrocytosis. They reported four important findings: (1) Clinically significant erythrocytosis (HCT >48%) was relatively uncommon in those with suspected or confirmed OSA occurring in only 8.0% of cases with only 1.6% having clinical erythrocytosis as defined as Hct ≥51% in males, Hct ≥48% in females. (2) The severity of obstructive sleep apnea as measured by Apnea Hypopnea Index was not associated with higher hematocrit levels or absolute erythrocytosis. (3) Both nocturnal hypoxemia and hypoxemia occurring while individuals were awake were independent predictors of erythrocytosis. (4) The severity of obstructive sleep apnea was predictive of nocturnal hypoxemia. These authors concluded that factors other than obstructive sleep apnea should initially be evaluated for unexplained secondary erythrocytosis, although nocturnal oximetry might be of diagnostic use. They concluded that in patients with unexplained nocturnal hypoxemia and erythrocytosis, an obstructive sleep apnea evaluation using a formal sleep study was warranted.[11] Conversely, PV may induce central sleep apnea by decreasing cerebral blood flow to diencephalic respiratory centers, and patients so affected can have complete resolution of their sleep disorder with normalization of their blood counts.

Pickwickian Syndrome and Polycythemia

Pickwickian syndrome or obesity–hypoventilation syndrome, seen in morbidly obese individuals, is characterized by chronic hypoxemia and hypercapnia caused by alveolar hypoventilation, with a resultant increase in EPO production, polycythemia, and cor pulmonale. The three principal causes are the high cost of the work of respiration in morbidly obese individuals, dysfunction of the respiratory centers, and repeated episodes of nocturnal obstructive apnea. Effective treatments include surgically induced weight loss, nasal continuous positive airway pressure ventilation, and the respiratory stimulant medroxyprogesterone acetate.

Polycythemia Caused by High Altitude

Polycythemia caused by the hypoxic conditions encountered by high-altitude dwellers would appear at first glance to represent a universal adaptive process to altitude. High altitude results in hyperventilation, alkalosis, and shifting of the O_2 dissociation curve to the left, leading to the impaired release of O_2 from hemoglobin and ultimately tissue hypoxia. This tissue hypoxia results in markedly increased EPO production, leading to increased plasma iron turnover, reticulocytosis, and a rising hematocrit level. Residents of the Andes Mountains who live 4200 m above sea level frequently have 30% higher hematocrit levels than individuals living at sea level.

People native to high altitudes (highlanders) live in a hypobaric hypoxic environment characterized by a low ambient partial pressure of oxygen. In response to this environment, they develop alveolar hypoxia, hypoxemia, and polycythemia. Healthy highlanders develop pulmonary hypertension, right ventricular hypertrophy, and an increased amount of smooth muscle cells in the distal pulmonary arterial branches, which leads to increased pulmonary vascular resistance and pulmonary artery pressure compared with individuals living at sea level. The importance of these structural changes in the pulmonary vasculature in highlanders is confirmed by the slow decline of pulmonary artery pressure, which is normalized after living for 2 years at sea level. Despite these adaptive changes, healthy highlanders are able to perform physical activities similar to or often even more strenuous than those living at sea level. In fact, there are differences in ventilation rates between athletes performing at sea level and those at high altitudes. Ventilation rates of athletes increase normally during exercise at sea level, but relative hypoventilation occurs in highlanders. This relative hypoventilation is characteristic of Andean natives and has been attributed to desensitization of the carotid bodies to the hypoxic stimulus. The erythrocytosis observed in individuals who reside at high altitudes for relatively short periods of time (days) can also be attributed in part to excessive water loss and contraction of the plasma volume. Total acclimatization of an individual who moves from sea level to a high altitude may actually require years. Individuals who reside at sea level and are acutely exposed to high altitudes are at increased risks of developing a deep venous thrombosis, pulmonary infarction, retinal hemorrhage, or ischemic digits because of increased blood viscosity. High-altitude climbers frequently combat these problems by intravenous administration of isotonic saline, with considerable success.

The chronic responses of various ethnic and racial groups to high altitudes are quite variable. Andean natives, known as the Quechua and Aymara Indians, experience a gradual increase in their hemoglobin levels with age. In addition, hemoglobin values are almost 10% higher in those living at 5500 m above sea level than in those living at 4355 m above sea level. Curiously, their Tibetan and Ethiopian counterparts living at similar altitudes do not respond to the resultant chronic hypoxia by increasing their hematocrits. It has been suggested that high levels of nitrous oxide in the exhaled breath of Tibetans may improve oxygen delivery by inducing vasodilatation and increasing blood flow to tissues, thus making the compensatory increased RBC volume unnecessary. Interestingly, Tibetans and Ethiopians have lived much longer as mountain dwellers than the Quechua or Aymara Indians, suggesting that extreme elevation of the RBC mass is a maladaptation that Tibetans and Ethiopians have avoided by adopting more physiologic compensatory mechanisms. Many residents of the Tibetan plateau reside at elevations exceeding 4000 m and experience oxygen concentrations that are about 40% lower than experienced at sea level. Human adaptation to a high-altitude environment is believed to be the result of advantageous genetic mutations and selective pressure. These genetic adaptations are shared by common ancestors within East Asian but not Central and South Asian populations and confer characteristics including adaptation to hypoxia, the absence of chronic mountain sickness (CMS), and high offspring survival rates. Polymorphisms in the *EPAS1* gene that encodes HIF-2α, and the *EGLN1* gene, which encodes PHD2, have been positively selected and have been shown to be associated with the key adaptive features in Tibetans. The putative advantageous haplotypes of *EGLN1* and *EPAS1* have revealed negative correlations with hemoglobin levels in Tibetans compared with lowlander Han Chinese. A variant in EGLN1, c.[12 C>G; 380 G>C], contributes functionally to the Tibetan high-altitude phenotype. PHD2 triggers the degradation of HIFs. The *PHD2* p.[Asp4Glu; Cys127Ser] variant exhibits a lower Km value for oxygen, suggesting that it promotes increased HIF degradation under hypoxic conditions. Whereas hypoxia stimulates the proliferation of WT erythroid progenitors, the proliferation of progenitors with the c.[12 C>G; 380 G>C] mutation in *EGLN1* is significantly impaired under hypoxic culture conditions. The c.[12 C>G; 380 G>C] mutation abrogates hypoxia-induced and HIF-mediated augmentation of erythropoiesis, which provides a molecular mechanism for the observed protection of Tibetans from polycythemia at high altitude.

This individual variability of elevation of serum EPO levels in high-altitude dwellers and the resultant increase in RBC mass appears widespread. For example, acclimatization to moderately high altitudes when combined with low-altitude training (so-called *living high*, *training low*) improves sea-level performance in endurance athletes, in part because of the erythropoietic effects of altitude exposure. This substantial individual variability in response to all forms of altitude training correlates with improved athletic performance and with elevation of EPO levels. A large component of this individual variability appears to be related to differences in the peak and rate of decay of the increase in EPO in response to altitude exposure. These observations suggest that genetically determined variables account for individual responses to hypoxia.

Chronic CMS is a pathological loss of adaptation to altitude. CMS is a clinical syndrome that occurs in a fraction of natives or lifelong residents living above 2500 m. Prevalence of CMS has considerable variability in different high-altitude parts of the world. The prevalence of CMS increases with age and varies among the mountainous regions of the world. CMS is an adult disease, and its prevalence is the lowest in Ethiopians (<1%) and Tibetans (~1%), higher in South Asian Indians (6.2%) and Han Chinese relocated to high altitudes (6%), and highest among South American Andeans (15%). This variability is mostly attributed to differences in ethnicity. Various ethnic groups have had different periods of adaptation to chronic hypoxia. Those living at high altitudes for the longest time are more likely to be better adapted. It appears that native Tibetans and Ethiopians are the most adapted ethnic groups as compared to Andeans and Han Chinese immigrants. CMS is characterized by excessive erythrocytosis (females, Hb >19 g/dL; males, Hb >21 g/dL); severe hypoxemia; and in some cases, moderate or severe pulmonary hypertension that may lead to the development of cor pulmonale and congestive heart failure. The clinical picture of CMS gradually disappears after descending to lower altitudes and reappears after returning to high altitudes. The prevalence of CMS is higher in men than women and increases with altitude, aging, associated lung disease, history of smoking, and air pollution. CMS is a public health problem in those living in mountainous regions of the world above 2500 m. In China alone, 80 million people live above that altitude, while in South America, 35 million people live above 2500 m. The CMS Andean phenotype has been associated with a single-nucleotide polymorphism (SNP) in the Sentrin-specific Protease 1 (*SENP1*) gene. The *SENP1* gene encodes for a protease that regulates the function of hypoxia-relevant transcription factors such as HIF and GATA1 and thus regulates erythropoiesis in individuals with CMS by modulating expression of EPO and the EPOR. The critical role of GATA1 in erythropoiesis is attributed to its ability to drive expression of many erythroid specific genes including enzymes involved in heme biosynthesis, hemoglobin, and the EpoR (see Chapter 27). *SENP1* has been shown to regulate EPO production by regulating the stability of HIF1 α during hypoxia, and indeed *SENP1*$^{-/-}$ mice die of anemia during early life. *SENP1* also mediates a positive-feedback loop under hypoxic conditions that is responsible for VEGF production and angiogenesis. SENP1-mediated regulation of EpoR expression is likely to occur through GATA-1. Compared with normoxic controls, hypoxic conditions induce a significant downregulation of SENP1 expression in non-CMS cells and an upregulation in CMS cells. Therefore, it is likely that hypoxia in patients with CMS induces a higher expression of SENP1 which favors exaggerated erythropoiesis. Thus Andeans, but not Tibetans and Ethiopians, possess a proerythropoietic SNP rather than SNPs that protect individuals from developing erythrocytosis. The presence of *SENP1* C/G or C/C SNPs are significantly associated with more severe forms of CMS. SENP-dependent stabilization of HIF2α would be anticipated to lead to increased Epo expression. Surprisingly, elevated Epo values are uncommon in CMS patients, yet a subgroup of CMS patients do have significantly higher Epo levels which is associated with slightly higher hematocrits. These CMS patients with high and normal EPO levels likely reflects genetic differences between these two populations. The development of CMS is associated with relative alveolar hypoventilation. Healthy highlanders characteristically hyperventilate. A gradual decline in the rate of alveolar ventilation in these individuals leads to progressive loss of adaptation to chronic hypoxia and the development of CMS. The main components of this syndrome include (1) alveolar hypoventilation leading to relative hypercapnia and increasing hypoxemia; (2) excessive erythrocytosis leading to increased blood viscosity and expansion of the total lung blood volume; (3) pulmonary hypertension and right ventricular hypertrophy that may evolve to hypoxic cor pulmonale and heart failure; (4) neuropsychiatric symptoms, including sleep disorders, headache, dizziness, and mental fatigue; (5) proteinuria in spite of a normal glomerular filtration rate; and (6) a contracted plasma volume which might potentially lead to more extreme polycythemia and clinical symptoms.[12]

Physical examination reveals cyanosis of the nail beds, ears, and lips in contrast to the ruddy complexion that is characteristic of a healthy highlander. In some cases, the face is almost black, and the mucosa and conjunctiva are dark red. The fingers are frequently clubbed, and auscultation of the heart reveals an increased pulmonary second sound. The patients are frequently hypertensive and have evidence of heart failure. Chest radiographic and electrocardiographic findings are characteristic of right atrial and right ventricular hypertrophy. Criteria for the diagnosis of CMS have been published and are useful in identifying CMS patients as well as monitoring their response to treatment.

The definitive treatment for CMS is descent to lower altitudes or sea level. The degree of polycythemia decreases after a few weeks or months, and eventually the hematocrit level returns to sea-level values. Pulmonary hypertension and right ventricular hypertrophy gradually resolve and disappear after 1 to 2 years of living at sea level. Phlebotomy or isovolemic hemodilution can reduce the excessive erythrocytosis and hyperviscosity, improve oxygenation, and lead to relief from symptoms. Due to its transient effects phlebotomy is not a long-term treatment for CMS since at high altitude hematocrit reaches or exceeds pretreatment values within a few weeks. A variety of drugs has also been evaluated for the treatment of patients with CMS. Ten weeks of the respiratory stimulant medroxyprogesterone acetate at doses of 60 mg/day was reported to lead to a reduction of hematocrit levels from 60% to 52% and an increase in arterial oxygen saturation from 84% to 90% in 17 highlanders with CMS. Medroxyprogesterone use, however, was associated with a loss of libido in men and therefore is infrequently used in this population. Therapy with almitrine, a respiratory stimulant, or enalapril, an ACE inhibitor (10 mg/day for 30 days), has resulted in even more modest reductions of hematocrit levels. Therapy with acetazolamide is the most useful treatment for CMS. Acetazolamide therapy has been evaluated in two double-blind, placebo-controlled, randomized clinical trials of patients with CMS. Acetazolamide is an inhibitor of carbonic anhydrase and stimulates ventilation by promoting the development of metabolic acidosis. Furthermore, acetazolamide reduces renal EPO production. Patients with CMS were randomized to receive placebo or acetazolamide therapy at a dose of 250 or 500 mg/day for 21 days. Drug therapy at both doses of acetazolamide resulted in reduction of hematocrit levels by 7% and serum EPO levels by 50% to 67%, with an increase in nocturnal oxygen saturation levels of 5%. Presently, 250 mg of acetazolamide daily appears to be an inexpensive, nontoxic, and effective therapy for CMS.

Smokers' Polycythemia or Carbon Monoxide-Induced Polycythemia

Smoking is the most common cause of secondary polycythemia. Those affected have a carboxyhemoglobin-induced increase in RBC mass or decrease in plasma volume, either of which is reversible with smoking cessation. Excessive carbon monoxide exposure can also be attributed to exposure to industrial emissions and automobile exhaust. Carbon monoxide binds to hemoglobin with a more than 200-times greater affinity than oxygen, resulting in not only occupation of one of the heme groups of hemoglobin but also an increase in the O_2 affinity by the remaining heme group. Individuals smoking even one pack of cigarettes a day frequently have elevated hematocrit levels. These patients characteristically have normal blood gases and elevation of carboxyhemoglobin levels, resulting in a reduction in $P_{50}O_2$. The elevation of the hematocrit level is reversed with interruption of the smoking behavior. Increased hematocrit levels have been observed in 3% to 5% of heavy smokers. Although these patients are not immune to thrombotic complications, the number of thromboembolic events is lower than in patients with PV. Polycythemia has also been reported to be associated with hookah use. A hookah is an oriental pipe containing tobacco often mixed with molasses and fruit flavors connected by a long flexible tube that draws the smoke to the bowl of water. Hookah use exposes the user to generous amounts of carbon monoxide, resulting in erythrocytosis.

Postrenal Transplantation Erythrocytosis

Postrenal transplantation erythrocytosis (PTE) is a potentially dangerous condition found in approximately 10% to 15% of renal allograft recipients. PTE usually develops within 8 to 24 months after a successful renal transplantation and resolves spontaneously within 2 years in about 25% of patients. There is no clear definition of PTE, but general consensus is hematocrit greater than 53% in men and greater than 51% in women that persists over a period of 3 to 6 months without other explanation for erythrocytosis. PTE is more common in males and may recur in the same patient after a second successful renal transplantation. Factors that increase the likelihood of its development are a lack of EPO therapy before transplantation, a history of smoking, diabetes mellitus, transplant-related renal artery stenosis, retention of the native kidney, low serum ferritin levels, and normal or high EPO levels prior to transplantation. PTE is also more frequent in patients who do not experience rejection. There is some evidence that the use of cyclosporine as an immunosuppressive agent is associated with increased risk of PTE. At higher hematocrit levels (usually >60%), thrombotic events may complicate the clinical course of patients with PTE.

Approximately 60% of patients with PTE experience malaise, headache, plethora, lethargy, and dizziness. In addition, from 10% to 20% develop thromboembolic complications involving either arteries or veins. Retention of the native kidney is essential for the development of PTE in most cases. Although the transplanted kidney produces EPO under normal regulatory mechanisms, the native kidney overproduces EPO despite the development of erythrocytosis. Frequently, the PTE resolves with removal of the native kidney. Plasma EPO levels can be normal or high in patients with PTE.

The molecular basis of PTE remains unclear; Ang II is believed, however, to play an important role in its pathogenesis by sustaining the secretion of EPO. Growing evidence indicates that increased AT1R expression makes erythroid progenitor cells hypersensitive to Ang II. Furthermore, Ang II can modulate release of EPO and IGF-1. Androgens are thought to play a role in the development of the syndrome. Androgens can directly affect erythroid progenitor cells or stimulate EPO production or actually the RAS. Treatment of patients with PTE includes intermittent phlebotomy or administration of an ACE inhibitor which suppresses the renin–angiotensin pathway and virtually eliminates the need for therapeutic phlebotomy in these patients. Maximal reduction of hemoglobin levels is evident 6 months after starting therapy with either an ACE inhibitor or angiotensin receptor blockers. Some patients are exquisitely sensitive to these medications and may become severely anemic. Therapy is usually begun at hematocrit levels above 55% with the hope of maintaining hematocrit levels below 50% to reduce the risk of thrombosis. ACE inhibitor fosinopril in an open-label crossover trial with theophylline was shown to produce a dramatic reduction in hematocrits in patients with PTE (51.3% to 43.7%; $P < .005$). Low doses of ramipril, another ACE inhibitor, normalized the hematocrit level in 26 out of 27 patients with PTE after a mean of 127 days of therapy.

Polycythemia Accompanying Kidney and Liver Diseases and Neoplastic Disorders

Polycythemia has been reported in association with kidney diseases such as renal cell carcinoma, renal artery stenosis, hydronephrosis, Wilms tumor, polycystic kidney disease, paragangliomas, and pituitary adenomas. Renal tumors account for approximately one-third of cases of tumor-associated polycythemias and secondary erythrocytosis can be seen in 1% to 5% of patients with renal cell carcinomas. The tumor tissue has been demonstrated to produce excessive amounts of EPO, and the erythrocytosis resolves with surgical resections of the tumor. The mechanisms underlying the activation of the *EPO* gene have been related to somatic mutations of the *VHL* gene in clear-cell renal carcinomas causing increased expression of EPO mRNA, HIF-1α, and HIF-2α. These abnormalities are related to a point mutation in the *VHL* gene that impaired the bindings of HIF-1α to VHL, leading to its accumulation and increased production of EPO. Polycythemia is also a well-described paraneoplastic manifestation of hepatocellular carcinoma in 2.5% to 10% of patients and is again caused by the production of EPO by the tumor. Polycythemia in hepatoma patients is strongly related to tumor burden and elevated α-fetoprotein levels. Polycythemia has also been associated with cerebellar hemangioblastomas and very large uterine fibromas. In tumor-associated erythrocytosis, EPO production has been shown to be autonomous of hypoxic stimuli. Paragangliomas are tumors arising from extraadrenal paragangliar neural crest cells. Most paragangliomas arise retroperitoneally or within the peritoneal cavity and are associated with high EPO levels and erythrocytosis. After tumor resection, reduction of the EPO levels and erythrocytosis occurs. Germ-line mutations involving two Krebs cycle enzymes, fumarate hydratase and succinate dehydrogenase, have been implicated in the hereditary paraganglioma–pheochromocytoma syndrome. In tumors deficient in these enzymes, fumarate and succinate accumulate, which inhibits PHD, leading to accumulation of HIF-1/HIF-2 and eventually resulting in erythrocytosis. In another patient with a paraganglioma who did not have the inherited syndrome but had extreme erythrocytosis, a germ-line mutation in *PHD2* was demonstrated. In this patient's tumor, tumor analysis showed LOH with the mutant allele predominating, which was associated with a loss of function. The degradation of both HIF-1α and HIF-2α was decreased. These data indicate that PHD2 can act as a tumor suppressor gene. The tumor suppressor activity of PHD2 has also been reported in sporadic endometrial, breast, and pancreatic cancers, with inactivating mutations ultimately leading to the increased production of growth factors that contribute to tumor growth.

Two plasma cell dyscrasias, **P**olyneuropathy, **O**rganomegaly, **E**ndocrinopathy, **M**onoclonal protein, **S**kin changes (POEMS) syndrome and **T**elangiectasias, **E**rythrocytosis with elevated erythropoietin levels, **M**onoclonal gammopathy of unknown significance [MGUS], **P**erinephric fluid collections, and **I**ntrapulmonary shunting syndrome (TEMPI) have recently been reported to be associated with erythrocytosis. Treatment is directed at the underlying disease. In TEMPI syndrome (22 patients reported in 11 countries worldwide as of December 2019), the most effective treatment has been plasma cell dyscrasia-directed therapies such as bortezomib, lenalidomide, and daratumumab, suggesting that TEMPI syndrome is a consequence of the abnormal plasma cell clone.[13]

Polycythemia in Endocrine Disorders

Polycythemia is also associated with Cushing syndrome, acromegaly, and primary aldosteronism. Secondary polycythemia can also be seen in men receiving long-term androgen-replacement therapy. A meta-analysis of randomized trials of testosterone therapy in hypogonadal men showed that participants in testosterone arms had statistically significant higher frequency of erythrocytosis compared to placebo.[14] The endocrine society guidelines suggest stopping therapy if hematocrit levels increase to greater than 54%. When hematocrit normalizes, a lower dose of testosterone can be attempted. Secondary polycythemia can also be seen in a significant number of competitive athletes taking anabolic steroids. For instance, in a small study of professional bodybuilders, 67% of those examined had hematocrit levels above 50%. Recombinant human EPO has also been abused by athletes competing in endurance sports and can be detected by analyzing the individual's hematocrit level, reticulocyte count, percentage of macrocytic RBCs, serum EPO level, serum transferrin receptor level, and electrophoretic mobility of the EPO molecule (recombinant EPO is less negatively charged than endogenous EPO).

Congenital Secondary Polycythemias

High-oxygen-affinity hemoglobins and bisphosphoglycerate deficiency. More than 100 mutations of hemoglobin lead to increased oxygen affinity and thus decreased oxygen delivery and compensatory polycythemia (see Chapter 44). These mutations involve either the α- or β-chain globin chains. Such polycythemias are usually well tolerated in young patients but may lead to thrombotic complications in older patients. High-oxygen–affinity hemoglobin variants are transmitted as autosomal dominants. Phlebotomy therapy of such patients has not been reported to be of any beneficial value and has been shown to decrease exercise tolerance. The best test to detect high-oxygen–affinity hemoglobin relies on the determination of hemoglobin dissociation kinetics and P_{50} (partial pressure of O_2 at which hemoglobin is 50% oxygenated). If cooximetry is not available, the P_{50} can be mathematically estimated from a venous blood gas measurement by using a computer algorithm, which is available online.

Whereas a $P_{50}O_2$ below 17 mmHg is indicative of a mutant hemoglobin with high oxygen affinity, a level above 35 mmHg is strongly suggestive of a mutant hemoglobin with a low oxygen affinity. Hemoglobin electrophoresis is not a reliable screen to rule out such a hemoglobin mutation because only about half of these mutants are electrophoretically distinguishable. Hemoglobin electrophoresis will reveal the presence of an abnormal hemoglobin only if the mutation leads to a change in electrical charge. If such a charge differential is not present, high-performance liquid chromatography or mass spectrometry followed by routine DNA sequencing of both α- and β-globin genes is required to establish the diagnosis.

A rare cause of congenital polycythemia is 2,3-BPG (previously known as 2,3-DPG) deficiency (see Chapter 44). 2,3-BPG is synthesized in RBCs and binds to hemoglobin, thereby reducing its affinity for oxygen. An absence of 2,3-BPG therefore leads to increased affinity of hemoglobin for oxygen, resulting in a lifelong hypoxic stimulus and erythrocytosis.

Congenital methemoglobinemias, whether caused by cytochrome b5 reductase mutations or globin mutations, may be associated with mild polycythemia (see Chapter 45). When hemoglobin is oxidized to methemoglobin, all of the four subunits of the tetramer may be affected, eliminating the oxygen transport capacity of hemoglobin.

Hypoxia-Inducible Factor Pathway Mutations Leading to Erythrocytosis

Alterations of a number of proteins in the HIF pathway have been shown to lead to increased EPO production and erythrocytosis (see Fig. 70.1). Chuvash polycythemia (CP) is an autosomal recessive disorder associated with germ-line mutations of *VHL* and erythrocytosis. CP was first described in the mid-1970s and is endemic in the Chuvash population of the Russian republic. The serum EPO concentration in affected individuals is elevated compared with healthy first-degree family members, although some patients may have normal serum EPO levels. They also have elevated levels of VEGF and plasminogen activator inhibitor-1. The erythroid progenitors of patients with CP are also hypersensitive to EPO; thus, CP has characteristics of both primary and secondary polycythemias. A homozygous missense mutation in the *VHL* gene, VHL598C→T mutation, was identified in CP patients. The disorder is characterized by high hemoglobin levels (usually >20 g/L), increased plasma EPO levels, varicose veins, vertebral hemangiomas, low blood pressure, and an elevated concentration of VEGF. The defective *VHL* gene product is not capable of promoting the ubiquitin-mediated degradation of HIF-1α and HIF-2α, thereby leading to increased levels of both of these proteins and increased elaboration of EPO. The CP-VHL mutants have been shown to affect EPO signaling in erythroid progenitor cells of patients with CP. JAK2 phosphorylation of STAT5 triggers not only erythroid progenitor development but also a negative feedback mechanism by transactivating the expression of SOCS family members, which bind and inhibit activated JAKs by promoting their ubiquitination and protosomal degradation. The CP mutation causes conformational changes, leading to a tight CP–VHL–SOCS-1 association, thereby slowing phosphorylated JAK2 degradation. These events lead to hyperactivation of the JAK2–STAT pathway in erythroid progenitor cells, causing their hypersensitivity to EPO, which likely contributes to the excessive erythrocytosis characteristic of CP. The frequency of the allele has been estimated to be at 0.057 in the Chuvash population. Several other similar types of mutations in VHL have been observed in a variety of other ethnic groups. A number of heterozygotes with erythrocytosis have been reported, which can likely be accounted for by an as yet undiscovered additional defect. CP is associated with a high mortality rate from thrombotic and hemorrhagic vascular complications. Most patients complain of chronic headache, fatigue, and/or lower extremity pain, and are noted to have lower blood pressures. Cerebrovascular events are especially common causes of death. The median age of death from cerebrovascular events is 42 years. Estimated survival to age 65 years is 29% for individuals with CP and 64% for age-matched community members. There is a perfect genotype–phenotypic correlation, with all patients with CP being homozygotes for the mutation. Interestingly, heterozygous carriers do not develop erythrocytosis but do have lower blood pressures and do not seem to be at increased risk for tumors, which contrasts with patients with VHL syndrome. Patients with CP also have larger livers, spleens, and kidneys than control patients, due to enhanced cellular proliferation caused by HIF-2α suppression of p21Cip1.

Germ-line mutations of *VHL* alleles have been reported in several patients with apparent congenital polycythemia that had no evidence of developing tumors; some of these subjects had germline mutations of both *VHL* alleles. Other subjects with congenital polycythemia of various ethnicities, including Pakistanis, Punjabis, African Americans, and Whites, harboring homozygosity for the CP *VHL* mutation or double heterozygosity for CP and other *VHL* mutations, have been found. The VHL598C→T mutation has been shown to originate in a single haplotype in the Chuvash patients, as well as in Whites, South Asian Indians, and one African American individual. Homozygosity of this mutation appears to be the most common genetic defect leading to congenital polycythemia. The mutation originated from a single founder 12,000 to 51,000 years ago. This suggests that such wide dissemination from the original founder may be associated with some survival advantage for heterozygotes carrying this mutation. Such an advantage might be related to a subtle improvement of iron metabolism, erythropoiesis, embryonic development, energy metabolism, or some other yet unknown effect.

VHL mutations are likely the most common cause of congenital polycythemias, greatly exceeding the number of patients with hemoglobin chain mutations. In point of fact, in one study of more than 200 unrelated subjects with apparently congenital polycythemia, none had a 2,3-BPG deficiency, two had a globin mutation (Hgb Vanderbilt and Hemoglobin San Diego), and 12 had *EPOR* mutations to account for their polycythemia. By contrast, when 50 patients were examined for the *VHL* mutation, 22 had *VHL* mutations, most of them being the CP *VHL* mutation, either being homozygous or in combination with another *VHL* mutation. The failure of patients with CP to develop VHL syndrome tumors is consistent with the concept that dysregulation of H1F-1α and VEGF are not sufficient to cause tumors. A cluster of patients with clinical features identical to patients with CP has been documented on the island of Ischia in the Bay of Naples, Italy. All of these patients also had the VHL598C →T mutation. Twelve of the 14 patients were homozygotes, and two were heterozygotes. The homozygotes had symptoms identical to patients in Chuvashia. Unlike heterozygotes in Chuvashia, the heterozygotes from Ischia developed erythrocytosis associated with high EPO levels, which raises the possibility that genetic alterations of additional components of the oxygen-sensing pathway other than VHL may contribute to the development of erythrocytosis in the Italian patients. The disorder in Ischia has a gene frequency even higher than that in Chuvashia, with 14% of the population estimated to be heterozygotes, which again has led to the suggestion that heterozygotes have a survival advantage, perhaps conferring protection from developing anemia. Recently a new VHL cryptic exon (termed E1') was identified deep in intron 1, which is naturally expressed in many tissues. Mutations in E1' were identified in seven families with erythrocytosis and in one family with typical VHL disease but without any alterations in other VHL exons. These mutations induced dysregulation of VHL splicing with excessive retention of E1' and downregulation of VHL protein expression.[15]

The Chuvash mutation has been shown to have a profound effect on the cardiopulmonary system. Patients with CP have significant abnormalities of cardiopulmonary physiology, including elevated basal ventilation rates and increased pulmonary vascular tone, with extremely high ventilatory rates and heightened pulmonary vasoconstriction and heart rates in response to acute hypoxia. These observations indicate that the VHL–HIF pathway might also play a central role in calibrating the pulmonary system to hypoxic challenges. Such undesirable exaggerated hypoxic responses and the resulting elevated pulmonary vascular hypertension may contribute to the morbidity and mortality associated with CP. Increased expression of endothelin-1 has been documented in patients with CP. Endothelins are vasoconstricting peptides produced primarily in the endothelium which play a pivotal role in vascular constriction. Hypoxia stimulates endothelin expression via HIF-1, while endothelins stabilize HIF-1 leading to expression of VEGF. Endothelin-1 has been associated with the development of hypoxia-related pulmonary hypertension. Endothelin-1 receptor inhibitors might therefore be useful in reversing the associated pulmonary hypertension in these patients. Treatment strategies for patients with CP have included phlebotomy, aspirin, and occasionally chemotherapy. Many patients are treated empirically with phlebotomy therapy, but this treatment is controversial and some experts believe that repeated phlebotomies can actually increase the risk of thrombotic events. The use of the JAK1/2 inhibitor, ruxolitinib, has been shown to be effective in reducing phlebotomy requirements in three patients with CP. More extensive evaluation of this treatment strategy is clearly warranted. Recently, administration of the allosteric HIF-2α inhibitor, belzutifan, to animal models of CP has been shown to decrease EPO production and reverse polycythemia. Drug treatment also decreased right ventricular pressure and pulmonary hypertension in these mice to near normal levels and normalized the movement of the cardiac interventricular septum. These data indicate that oral intake of belzutifan might be a potential effective treatment of CP patients with polycythemia, pulmonary hypertension, pulmonary fibrosis, and complications caused by elevated expression of HIF-2α.[16]

Additional genetic abnormalities of oxygen sensing have been reported that lead to familial polycythemia. A heterozygous C-to-G change at base 950 of the coding sequence of *PHD2* (*P317R* mutation) was first detected in three affected family members with this syndrome. Hydroxylation of HIF-1 by PHD2 facilitates its interaction with VHL, thereby favoring its ubiquitination and degradation by the proteosome. The failure of *PHD2 P317R* to bind HIF-1 and HIF-2α and promote HIF hydroxylase activity ultimately leads to increased HIF-1/HIF-2 and EPO levels, resulting in the development of erythrocytosis. The *PHD2 P317R* mutation is inherited as an autosomal dominant trait in contrast to the CP defect, which is an autosomal recessive disorder. Polycythemic patients with *PHD2 P317R* do not have any evidence of tumors characteristic of the VHL syndrome. Additional mutations in *PHD2* have been reported that lead to erythrocytosis. Over 20 erythrocytosis-associated PHD2 heterozygous missense, nonsense, and frameshift mutations have been reported. A series of HIF-2 gain-of-function mutations have also been reported to lead to familial erythrocytosis in an autosomal dominant fashion. These mutations lead to weakened bonds between PHD2 and HIF-2, resulting in less hydroxylation of HIF-2 and subsequent recognition of HIF-2 by VHL. Many of these patients present in their twenties, although patients have also been diagnosed in their fifties with erythrocytosis associated with high EPO levels. Interestingly some HIF-2α mutations are also associated with neuroendocrine tumors.

Neonatal Polycythemia

Because of the high oxygen affinity of fetal hemoglobin, many neonates have markedly elevated hematocrit levels. Babies with hematocrit levels over 65% have neurologic and functional impairments, and are more likely to be born to diabetic mothers. Although phlebotomy has been recommended, there is little evidence that it is beneficial for these babies.

Drug-induced Erythrocytosis

The administration of EPO, corticosteroids, or androgens to an excessive degree has each been associated with reversible erythrocytosis. Androgens have been shown to stimulate EPO production and to directly affect erythroid progenitor cells. Approximately 5% of patients receiving long-term testosterone therapy for testosterone-deficiency syndrome develop erythrocytosis. A higher proportion of erythrocytosis has been reported in transmasculine individuals receiving intramuscular testosterone enantate (23.3%) as compared to transdermal testosterone (0%).[17] Androgens activate HIF-1 and HIF-1-regulated gene expression, leading to increased expression of VEGF and presumably EPO. Rarely, erythrocytosis can be the presenting manifestation of Cushing syndrome. Blood doping refers to the use of EPO to increase the RBC mass and enhance oxygen delivery with the hope of increasing endurance performance in athletes. A monitoring of an athlete's hematologic profile longitudinally provides some insight into the likelihood of blood doping playing a role in the development of erythrocytosis.

The development of paradoxical polycythemia in three patients with VHL syndrome and CNS or retinal hemangioblastomas treated with a VEGF receptor inhibitor has been reported. The cause of these phenomena remains unknown. In addition, reversible paradoxical erythrocytosis has been reported with the use of VEGF tyrosine kinase inhibitors, including sunitinib, sorafenib, axitinib, pazopanib, and the anti-VEGF monoclonal antibody bevacizumab, primarily in patients with renal cell carcinomas. These patients become symptomatic due to fatigue, pruritis, myalgias, headaches, and malignant hypertension. The cause of the erythrocytosis associated with these drugs has been attributed to either elevation of EPO levels or sensitization of erythroid cells to EPO. The erythrocytosis in this situation can be controlled with phlebotomy therapy with relief of symptoms.

POLYCYTHEMIA VERA

PV is a clonal, chronic, progressive myeloproliferative neoplasm (MPN) often of insidious onset, characterized by an absolute increase in RBC mass and often by leukocytosis, thrombocytosis, splenomegaly, and driver mutations affecting JAK2. PV leads to excessive proliferation of erythroid, myeloid, and megakaryocytic elements within the BM. Vaquez first described this clinical entity in 1892, noting the characteristic physical findings. At the turn of this century, Cabot and Osler independently associated the name PV with this clinical disorder.

PV differs from many other hematologic malignancies in that prolonged survival is enjoyed by most patients if the excessive production of RBCs and platelets can be controlled. This prolonged survival, however, can be punctuated by the development of other syndromes, such as myelofibrosis (MF), termed *post-PV MF*, and a form of acute leukemia termed MPN-blast phase (MPN-PB) (Fig. 70.3). Frequently, patients present at the time of a thrombotic event or when asymptomatic to a physician only to find that they have splenomegaly, isolated erythrocytosis, or thrombocytosis. Left untreated, these patients will become progressively symptomatic owing to the excessive production of RBCs, platelets, and white blood cells, leading to arterial or venous thromboses, aquagenic pruritus, and systemic symptoms caused by increasing splenomegaly. After a number of years, the erythrocytotic phase of the disease can become inactive, and the patient may no longer have the sequelae of excessive RBC production. Subsequently, these patients can develop post-PV MF, which is frequently indistinguishable from another MPN, primary MF (PMF) (see Chapter 72). Finally, a significant proportion of these patients will go on to develop MPN-BP. Most patients undergo this orderly transition, but some patients transition from the polycythemic phase directly into an MPN-BP or a myelodysplastic disorder. The outcome of patients with PV is largely influenced by the increased risk of thrombosis, evolution to PV-related MF, and MPN-BP. Patients who are at the greatest risk to progress to post PV-MF or MPN-BP frequently have additional mutations in myeloid malignancy genes including TP53 and genes encoding chromatin and spliceosome regulators.[18]

The transition from one phase of MPN to another is not necessarily unidirectional. About 10% to 15% of patients with *JAK2V617F*-positive essential thrombocythemia (ET) eventually develop erythrocytosis and are reclassified as having PV (see Chapter 71). A number of cases of presumed PMF either spontaneously or after chemotherapy have been described where the patient develops erythrocytosis and a syndrome that is virtually indistinguishable from de novo PV. The constantly changing clinical picture of this malignant hematologic disorder requires careful observation and treatment to deal with the numerous problems that can be encountered.

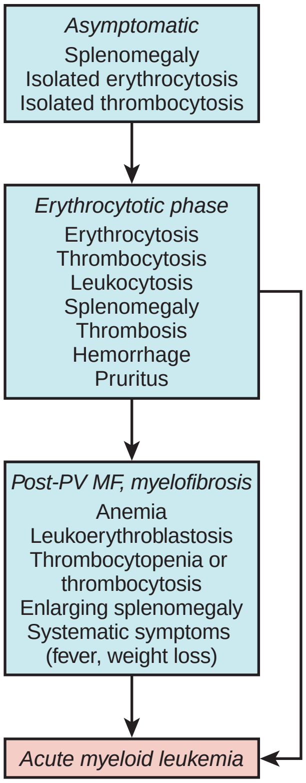

Figure 70.3 EVOLUTION OF POLYCYTHEMIA VERA. *MF*, Myelofibrosis; *PV*, polycythemia vera.

Epidemiology

PV is the most common primary polycythemia. Incidence rates (IRs) have been reported to be around 2.8 per 100,000 persons per year. It is important to emphasize that no or very few population-based estimates of the prevalence of this disorder are presently available. Actual determination of its prevalence has been a difficult process because of the need in the past to pursue an extensive diagnostic evaluation to differentiate this disorder from other causes of spurious or absolute erythrocytosis. The diagnosis of PV has been simplified by the identification of PV-associated mutations (*JAK2V617F* and *JAK2* exon 12 mutations), permitting for the first time molecular epidemiologic studies. The prevalence of the *JAK2V617F* mutation in a normal population in Denmark was recently determined to be 0.2%, with 63% of these individuals not having a previously detected hematological malignancy. The presence of the mutation was associated with increasing age, male sex, and a lower cumulative survival. Recently available 2001 to 2012 data from the Surveillance, Epidemiology and End Results (SEER) Program from the US National Cancer Institute provided new insight into the IR of the MPNs. This study utilized the World Health Organization (WHO) Diagnostic Criteria and during the last 5 years of the study *JAK2V617F* testing was included. The age-adjusted IR of PV and ET were 10.9 and 9.6 per 1 million per year, respectively. The IR for PMF was 3.1. In order to grasp the magnitude of the IR of these various MPNs, the IR of CML was 3.3, demonstrating that the IR of these Ph^- MPNs were sevenfold higher than CML. Both PV and PMF were more frequent in males while the IR for ET was greater in females. ET, PV, and PMF were associated with lower IRs among Hispanic whites than non-Hispanic whites.[19] Several groups have reported that 50% of patients with a splanchnic vein thrombosis without an overt MPN are *JAK2V617F* positive and that more than 50% of these individuals subsequently develop an MPN. However, the incidence of the mutation with unprovoked thromboembolism in the more usual sites (deep venous thrombosis involving the leg veins or pulmonary embolism) ranges between 0.2 and 1.0%. Such data have led to the conclusion that systematic screening for *JAK2V617* in such a patient population is not warranted.

The prevalence of PV has been reported by several investigators to be higher among American Jews and lower among African Americans and Hispanics. The reported lower incidence in African Americans might reflect a referral bias characteristic of centers with research interest in MPN because the authors, when practicing in several large urban areas, have observed a considerable number of African Americans with MPNs, including PV. The incidence of the disorder is greater among Ashkenazi Jews, who originate from eastern and central Europe, than among Arabs and Sephardic Jews. Interestingly, extremely low IRs have been reported from Japan. These findings suggest that important genetic factors might be involved in the biogenesis of this disorder. The importance of genetic factors in the origin of this disease is further emphasized by reports of multiple cases of *JAK2V617F* or *JAK2* exon 12 mutation-positive and -negative MPN, including PV, within multiple generations of a number of families. These forms of familial PV must be distinguished from PFCP, CP, and polycythemia associated with mutations in the HIF pathway. The reports of families in which multiple members have PV first raised the possibility that a genetic predisposition to acquire such mutations exists in these families that is inherited in an autosomal dominant pattern with decreased penetrance. Clinical analyses of affected family members confirmed that they have clonal hematopoiesis (CH) and that their clinical manifestations are identical to patients with sporadic PV. In a large population study from Sweden, the relatives of MPN patients were shown to have a significantly increased risk of developing a Ph^- MPN and possibly chronic myeloid leukemia. It was estimated that first-degree relatives of MPN patients have a five- to sevenfold greater risk of developing an MPN, again supporting the hypothesis that common strong susceptibility genes predispose one to develop PV, essential thrombocytosis (ET), PMF, and possibly CML.

One notable exception to the low prevalence of PV in Japan has been the higher incidence observed among populations exposed to atomic bomb explosions. The possibility that radiation exposure is an etiologic factor in the generation of PV was also raised by the observation in the United States of four cases of PV 10 to 20 years after the Smokey nuclear weapons test in which 3000 military observers were exposed. An epidemiologic investigation that focused on occupational exposure among petroleum refinery and chemical plant workers has revealed an increased incidence of PV relative to the general population. In this study, the increased incidence of PV was linked to similar increases in the frequency of multiple myeloma and non-Hodgkin lymphoma, suggesting involvement of a putative environmental toxin that may have broad hematopoietic toxicity. The possibility of environmental factors contributing to the development of PV was raised by the identification of a cluster of patients with *JAK2V617F*-positive PV in an area of Eastern Pennsylvania that contained numerous sources of hazardous materials, including waste coal power plants and United States Environmental Protection Agency Superfund sites.

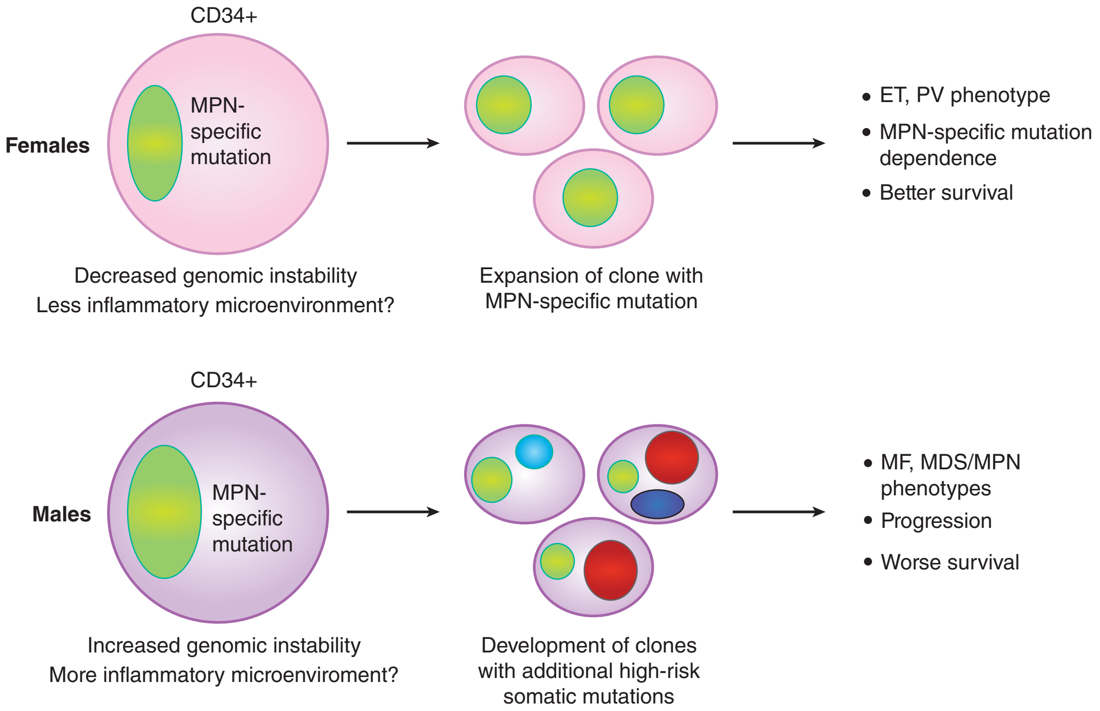
In several large studies, 5% of patients with PV were younger than 40 years of age, 1% were younger than 25 years at diagnosis, and 0.1% were younger than 20 years. Small numbers of patients with PV have been reported who presented during childhood. Interestingly, females comprise the majority of PV patients diagnosed before the age of 40 years, suggesting a unique risk factor for developing the disease at early age. These young female patients tend to present with unique complications such as splanchnic vein thromboses (SVT). However their risk of transformation to PV-MF or MPN-BP has been thought to be similar to males. Additional risk factors for female PV patients developing SVTs is their use of oral contraceptives and estrogen replacement therapy. Karantos and coworkers has reported provocative data which indicates that male sex serves as a poor prognostic parameter for PV patients. Men had higher JAK2 V617F allele burdens in their $CD34^+$ cells, acquired more somatic mutations apart from the MPN driver mutations, and had an increased frequency of acquiring high-risk mutations. By contrast, disease progression in females was reported to be more dependent on higher JAK2V617F variant allele burdens (VAFs) rather than on acquisition of other somatic mutations (Fig. 70.4).[20]

The *JAK2V617F* mutation has a prevalence of 0.1% to 0.2% in the general population. These individuals usually have a VAF of less than 10%. Some of these patients have an undiagnosed MPN or represent an early molecular stage of a MPN, which will evolve over time. The normal individuals with a low JAK2V617F VAFs are thought to have CH of indeterminate potential (CHIP) (see Chapter 19). Although these individuals with JAK2V617F+ CHIP do not have an overt MPN they have significantly higher platelet counts, white blood cell counts, and hematocrit levels and are at higher risk of developing arterial and venous thrombotic events than normal individual with wild type JAK2. Most of these CHIP patients never develop an MPN but some eventually develop a full-blown MPN.[21]

Pathobiology

Considerable speculation has centered on the pathobiology of the erythrocytosis that characterizes PV. The expanded RBC mass in PV patients is due to a two- to three-fold increase in the production of RBCs by a hyperplastic BM and is not attributable to prolongation of the RBC lifespan. Granulocyte and platelet production are also increased in this disorder. This overly exuberant production of all cellular elements of the blood suggests that the basic defect resides at the level of the pluripotent hematopoietic stem cell (HSC).

Serum EPO levels have been shown to be subnormal in patients with PV, elevated in many but not all cases of secondary erythrocytosis, and normal in patients with relative polycythemia, indicating that PV cannot be an abnormality of EPO production.



CD34+
Females
MPN-specific mutation
Decreased genomic instability
Less inflammatory microenvironment?
Expansion of clone with MPN-specific mutation
• ET, PV phenotype
• MPN-specific mutation dependence
• Better survival
CD34+
Males
MPN-specific mutation
Increased genomic instability
More inflammatory microenviroment?
Development of clones with additional high-risk somatic mutations
• MF, MDS/MPN phenotypes
• Progression
• Worse survival

Figure 70.4 HYPOTHETICAL MODEL OF THE DIFFERENT BIOLOGY OF MPN DEVELOPMENT AND PROGRESSION BETWEEN WOMEN AND MEN. *ET*, Essential thrombocythemia; *MDS*, myelodysplastic syndromes; *MF*, myelofibrosis; *MPN*, myeloproliferative neoplasm. *(From Karantanos T, Chaturvedi S, Braunstein EM, et al. Sex determines the presentation and outcomes in MPN and is related to sex-specific differences in the mutational burden. Blood Adv. 2020;4[12]:2567–2576.)*

In 1951, Dameshek postulated that chronic myeloid leukemia, PV, essential thrombocythemia, and PMF were related disorders, which he called *myeloproliferative disorders*, but are now termed *MPNs* because of the evidence that these disorders are hematologic malignancies.

Since the mid-1970s, data have accumulated that conclusively demonstrate PV to be the result of a neoplastic proliferation of hematopoietic cells. The cellular origin of the disorder was first established by the analysis of glucose-6-phosphate dehydrogenase (G6PD) isoenzymes in women who were heterozygous for this X-linked gene. This approach was based on the random irreversible inactivation of one X chromosome in each female somatic cell during embryogenesis. Inactivation of the same X chromosome occurs in the progeny of these cells. A normal female heterozygous for G6PD will therefore have approximately equal populations of BM cells with a different G6PD isoenzyme. The G6PD isoenzymes can be readily distinguished by electrophoretic methods.

This approach was exploited in a seminal study by Adamson and coworkers in an effort to determine the cellular origin of PV. They presumed that cells comprising a tumor that arises from a single cell in a G6PD heterozygote would express a single isoenzyme type, but a neoplasm originating from multiple cells would express both isoenzyme types. These investigators found that circulating RBCs, granulocytes, and platelets obtained from female patients who were G6PD heterozygotes express the same isoenzyme, but skin and cultured BM fibroblasts obtained from these same patients demonstrate both isoenzymes. They concluded that PV represented a clonal proliferation of neoplastic HSCs and was not multicellular in origin or the consequence of excessive proliferation of normal HSCs.

The clonality of blood cell production in PV has subsequently been confirmed using restriction fragment length polymorphisms of the active X chromosome. A monoclonal pattern of X chromosome inactivation has been defined in RBCs, granulocytes, monocytes, and platelets in female patients with PV.

On the basis of the knowledge that RBC production in PV is not associated with excessive EPO production, numerous investigators hypothesized that the erythroid progenitor cell in this disorder was no longer subject to physiologic regulators. PV BM can form substantial numbers of erythroid colonies in vitro in the absence of exogenous EPO, but normal human BM is incapable of forming such colonies without the addition of EPO. These erythroid colonies were termed *endogenous colonies*. When erythroid PV and normal BM were subsequently assayed in the presence of EPO, PV BM was characterized by a higher cloning efficiency. Additional observations suggested that the altered response to cytokines was not restricted to EPO but included a variety of other cytokines and that this cytokine hypersensitivity was characteristic of progenitor cells committed to a variety of other lineages.

In addition, BM cells cloned from G6PD heterozygous females with PV in the presence and absence of exogenous EPO revealed that the erythroid colonies that formed in the absence of exogenous EPO contained the same G6PD isoenzyme type as that expressed by peripheral blood elements. Thus, the so-called *endogenous erythroid colonies* arose from the abnormal clone that was responsible for supplying RBCs, granulocytes, and platelets to the peripheral blood. When exogenous EPO was added, increasing numbers of colonies were formed containing cellular elements expressing the other G6PD isoenzymes; presumably, these colonies originated from cells not involved in the malignant process. Similarly, small numbers of granulocyte–macrophage colonies not originating from the PV clone were also observed in these assays. These data collectively indicate the existence of malignant and nonmalignant populations of HPCs in PV BM. The relative frequency of the neoplastic clone in relation to normal progenitor cells was further examined by Adamson and coworkers, who, by monitoring the proportion of neoplastic erythroid clones and their numeric relationship to normal clones over a period of several years, showed disease progression was associated with a significant decline in the frequency of normal progenitor cells and increasing proportion of the neoplastic clone. Erythroid progenitor cells from PV patients are, in fact, abnormally sensitive to the actions of this EPO. This increased responsiveness allows these cells to form colonies in the presence of small amounts of EPO. Most PV patients possess two distinct populations of erythroid progenitor cells: a normally EPO-responsive population and a population of cells similar in proliferative and maturational behavior in vitro but requiring little or no EPO. These investigators suggested that the proliferation of the normal progenitor cells in vivo was at a disadvantage. A number of investigators have demonstrated that the increased responsiveness of these BM progenitor populations extends to their responses to other cytokines, including SCF, IL-3, GM-CSF, IGF-1, G-CSF, and thrombopoietin (TPO).

Identification of *JAK2V617F* Mutation in Polycythemia Vera

For more than two decades a number of research groups searched for the genetic defect underlying PV. Most groups predicted that this defect involved the signaling pathways downstream of the EPOR. These pathways include the tyrosine kinase JAK2 and the transcriptional signal transducers and activators of transcription, STAT3 and STAT5. The initial discovery of a mutation was predicated on a somewhat simplistic yet revealing set of experiments performed by Vainchenker and colleagues in France.[22] They observed that the inhibition of JAK2 by a small molecule (AG490) or by small interfering RNA (siRNA) reduced EPO-independent colony formation by PV BM mononuclear cells. This observation prompted them to directly sequence JAK2 in the hematopoietic cells of PV patients and to discover a single recurrent point mutation. A guanine-to-thymine mutation was observed that resulted in a substitution of valine to phenylalanine at codon 617 within the pseudokinase domain (JH2) of *JAK2* (*JAK2V617F)* (Fig. 70.5). These findings were quickly confirmed by several different groups. Kralovics et al. had previously identified a region of LOH on chromosome 9p in PV and identified a 6.2-Mbp region common to all PV patients screened.[23] Because this region contained *JAK2*, with its known role in erythropoiesis, it was screened for mutations and the same *JAK2V617F* mutation identified. Three other groups targeted *JAK2* as part of a global sequencing screen of tyrosine kinases and phosphatases in MPNs. *JAK2V617F* is an acquired somatic mutation present exclusively in hematopoietic cells. All JAK2V616F+ patients with PV have a population of erythroid progenitor cells that are homozygous for the mutation. Using quantitative PCR, patients can be divided into those with a low allele burden of *JAK2V617F* in granulocytes (<50%) and patients with a higher burden of *JAK2V617F* (>50%). A subset of patients with PV are homozygous for *JAK2V617F*, which is the result of mitotic recombination and duplication of the mutant allele (Fig. 70.6). The occurrence of mitotic recombination has been observed during the clinical course of individual patients, leading to *JAK2V617F* heterozygous patients becoming homozygous over time. The concept of the conversion of *JAK2V617F* low burden to high burden is further supported by the observation that the median duration of disease at the time of evaluation was 48 months in high-burden PV patients compared with 23 months in low-burden PV. These observations are consistent with a multistep pathogenesis of PV. The first step consists of the acquisition of *JAK2V617F*, which results in a low allele burden of *JAK2V617F*, followed by a second step, homologous recombination, that leads to *JAK2V617F* homozygous progenitor cells and eventually granulocytes with a high burden of *JAK2V617F*.

Several groups have recently reported that *JAK2V617F* can be acquired several decades before the appearance of an overt MPN. In fact in some individuals it has been suggested using mathematical modeling that the mutation in *JAK2* is acquired in utero. It remains unknown at present if a lesion occurring prior to acquisition of the *JAK2V617F* mutation predisposes an individual to acquire *JAK2V617F*.

JAK2V617F is present in greater than 95% of PV cases. Approximately 50% to 60% of patients with ET and PMF are also *JAK2V617F* positive. ET is distinguished from PV by being associated with a low allele burden. In the overwhelming majority of cases,

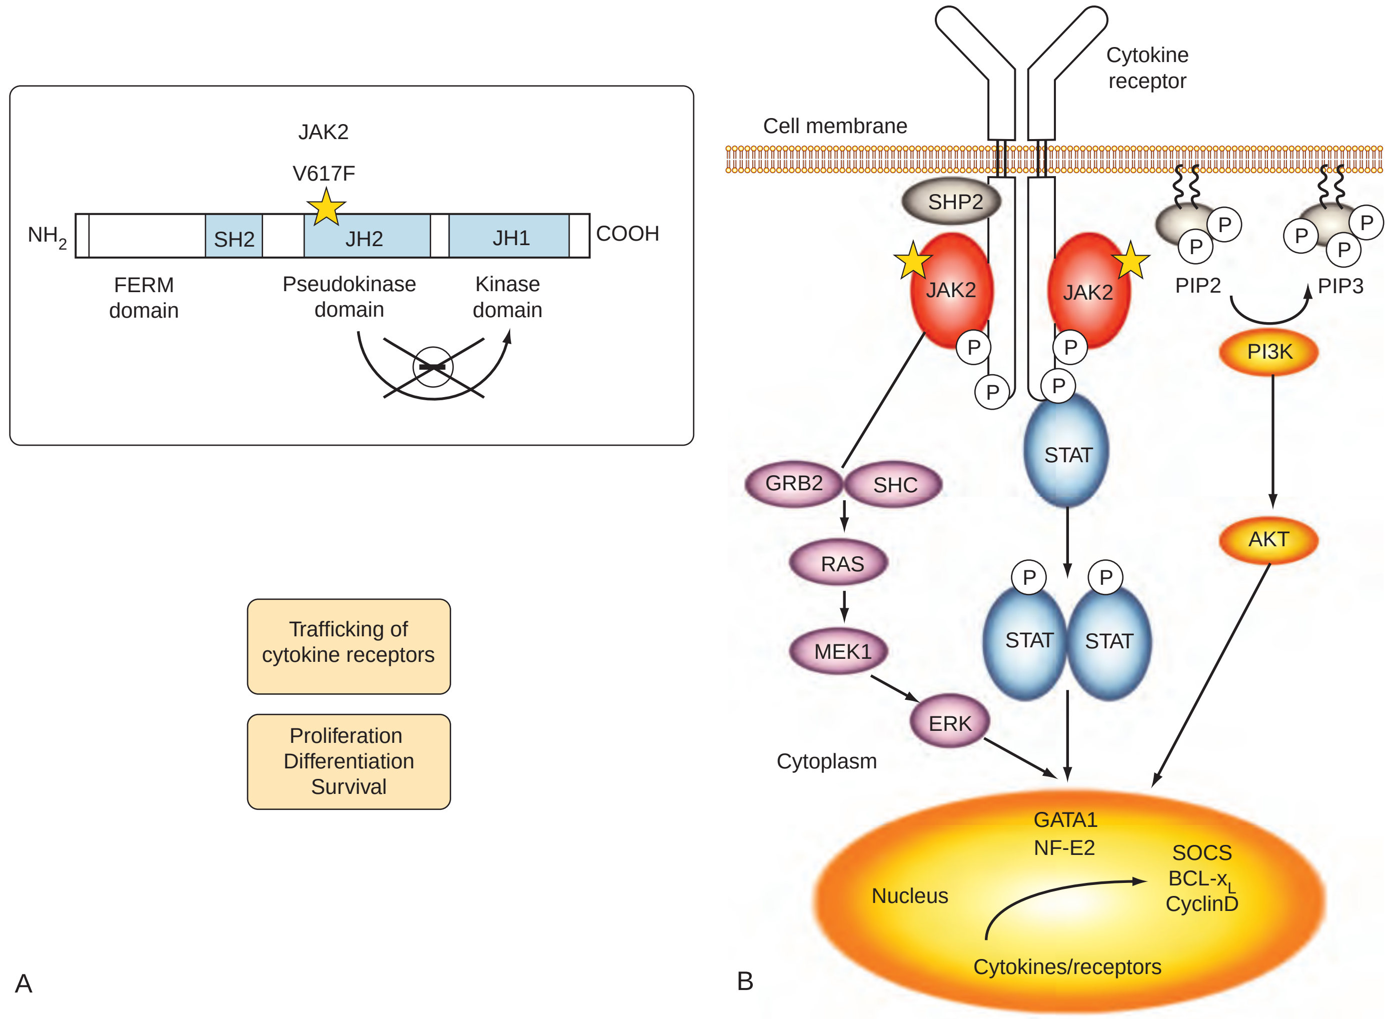


Figure 70.5 *JAK2V617F* SIGNALING IN MYELOPROLIFERATIVE DISORDERS. (A) Structure of *JAK2V617F*: the mutation is located in pseudokinase JAK JH2 and disrupts the autoinhibition of this regulatory domain. Consequently, the tyrosine kinase corresponding to the JH1 domain is constitutively activated. (B) In the presence of a homodimeric cytokine receptor (e.g., erythropoietin receptor), the two *JAK2V617F* proteins bound to the intracellular domain of the receptor transphosphorylate its tyrosine residues. In turn, STAT5, PI3K, and RAS signaling pathways are activated, leading to the downstream modulation of transcription and protein levels for cell cycle, proliferation, and apoptosis-related factors. *Bcl-X*$_L$, B-cell lymphoma-extra large; *ERK*, extracellular signal-related kinase; *GATA*, GATA-binding factor; *GRB*, growth factor receptor-bound protein; *JAK*, Janus kinase; *JH2*, JAK homology domain 2; *MEK1*, dual specificity mitogen-activated protein kinase kinase 1; *NF*, nuclear factor; *P*, Phosphate; *PI3K*, phosphatidylinositol 3-kinase; *PIP2* and *PIP3*, phosphatidylinositol bi- and triphosphate; *RAS*, renin–angiotensin system; *SH2*, src homology 2; *SOCS*, suppressor of cytokine signaling; *STAT*, signal transducer and activator of transcription. *(From Delhommeau F, Pisani DF, James C, et al. Oncogenic mechanisms in myeloproliferative disorders. Cell Mol Life Sci. 2006;6363:2939.)*

PV is characterized by a population of *JAK2V617F* homozygous colonies with some heterozygous and WT colonies. By contrast, in ET, there are few homozygous colonies, with the majority being heterozygous or WT. The majority of ET and PMF patients who are negative for *JAK2V617F* have CH, which indicates that these *JAK2V617F* negative diseases likely are the consequences of other genetic events including mutations in the TPO receptor, MPL, or calreticulin, which are discussed in Chapters 71 and 72. The *JAK2V617F* allele has also been observed in a limited number of patients with chronic myelomonocytic leukemia, myelodysplastic syndromes (MDS), refractory anemia with ring sideroblasts and thrombocytosis (see Chapter 73), and acute myeloid leukemia (AML), although most *JAK2V617F* mutations in AML occur in patients with a preceding diagnosis of PV, ET, or PMF. *JAK2V617F* is an acquired somatic mutation, does not appear in nonhematopoietic cells, and has not been detected in patients with secondary erythrocytosis. Moreover, *JAK2V617F* has not been observed in lymphoid malignancies, although other mutations in *JAK2* have been identified in 10% of patients with pediatric high-risk ALL (see Chapter 66).

Other *JAK2* Mutations in Polycythemia Vera

Other mutations of *JAK2* associated with erythrocytosis, however, can also constitutively activate JAK2 kinase activity. Several gain-of-function mutations affecting *JAK2* exon 12 within an area immediately adjacent to the pseudokinase domain of *JAK2V617F*-negative patients have been identified in 2.5% to 3.4% of PV patients and approximately 30% of *JAK2V617F*-negative PV cases. To date, greater than 40 different such mutations have been identified. Two-thirds of patients with a *JAK2* exon 12 mutation presented with an isolated erythrocytosis and distinctive BM morphology, and had reduced serum EPO levels, but the remainder of patients have erythrocytosis plus leukocytosis, thrombocytosis, or both. These exon 12 mutations perturb the autoinhibitory domain of *JAK2*. *JAK2* exon 12 mutations have not been reported in patients with ET or PMF, but have been occasionally observed in patients with refractory anemia and ring sideroblasts associated with thrombocytosis. Erythroid colonies cloned from their blood samples in the absence of exogenous EPO were most frequently heterozygous for the mutation, with homozygous colonies only rarely

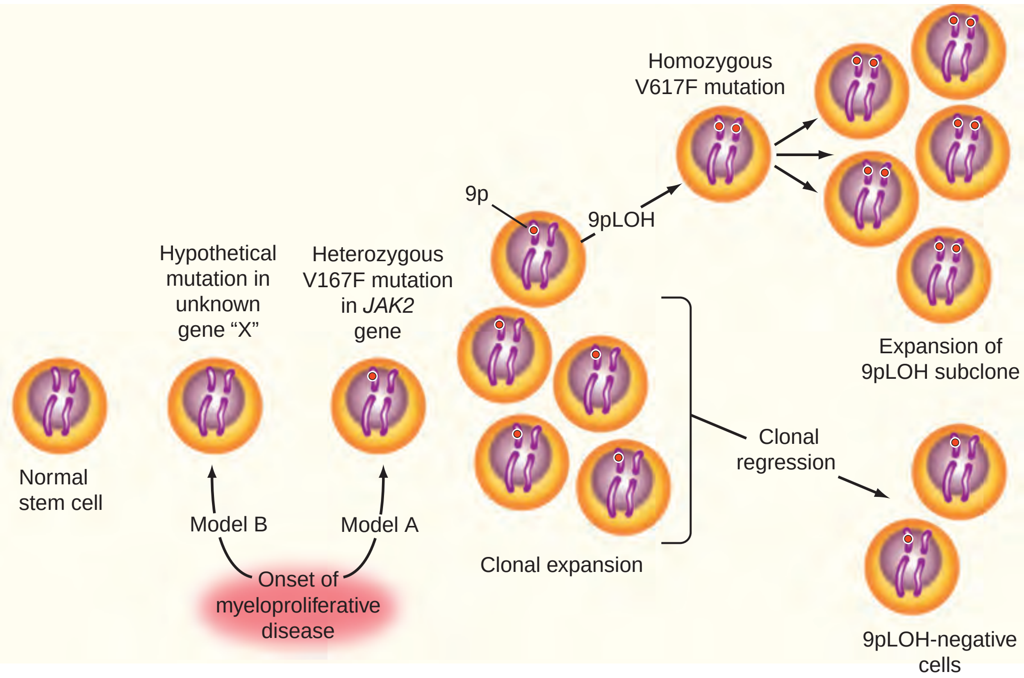

Figure 70.6 POSSIBLE ROLE OF *JAK2V617F* IN THE BIOLOGY OF MYELOPROLIFERATIVE DISORDERS. The chromosome 9 with the wild-type *JAK2* sequence (G) is depicted in *white*, and the chromosome 9 with the G–T transversion (T) is shown in *red*. *Circles* symbolize the nuclei of the cells. Deletion of the telomeric part of wild-type chromosome 9p as a potential mechanism for 9pLOH is shown on the *left*. Alternatively, mitotic recombination could also result in 9pLOH, shown on the *right*. The events during mitosis and the resulting cell progeny after mitotic recombination of chromosome 9p are also shown. *(Adapted from Kralovics R, Passamonti F, Buser AS, et al. A gain-of-function mutation of JAK2 in myeloproliferative disorders. N Engl J Med. 2005;352:1779.)*

occurring, but colonies homozygous for the mutation occur in most PV patients with *JAK2V617F*, suggesting that a *JAK2* exon 12 mutation results in a stronger activation of the JAK2-mediated intracellular signaling pathways. Exon 12 mutations tend to occur in younger patients compared to *JAK2V617F* positive PV patients. After taking the younger age of exon 12 *JAK2* mutated PV patients into account, the clinical outcomes of patients with these two different *JAK2* mutations have been shown to be similar. Patients with exon 12 mutations can develop thrombotic episodes and can evolve into PV-related MF or MPN-BP. In several series, approximately 2.7% of patients with a clinical syndrome that resembles PV have been observed who have a WT *JAK2*. The existence of such patients may be the result of several factors, including limited sensitivity of the assay used for genotyping, or lack of efforts to exclude inherited genetic disorders associated with erythrocytosis that have been described in this chapter. Alternatively, additional acquired genetic lesions that have yet to be described may be responsible for the disease phenotype.

JAK2V617F Is Likely Not the Only Event That Determines if Polycythemia Vera Develops

Although data generated using a variety of mouse models suggests that *JAK2V617F* might be sufficient for the development of PV, increasing evidence shows that PV is not solely dependent on acquisition of *JAK2V617F*. The fact that *JAK2V617F* has been identified in patients with three phenotypically related but clinically distinct MPNs suggests that additional genetic or epigenetic events likely contribute to the phenotypic divergence of PV, ET, and PMF. These differing disease phenotypes have been hypothesized to be caused by striking differences in the degree to which the mutation activates the JAK-STAT pathway. Mutant *JAK2* activates multiple cytokine receptor-associated pathways, including STAT1 and STAT5, which can have competing consequences. STAT1 appears to be activated in association with *JAK2V617F* ET but not PV. Inhibition of STAT1 in ET progenitor cells enhances erythropoiesis, indicating that in ET, the phospo-STAT1 response to *JAK2V617F* constrains erythropoiesis and promotes megakaryocytic differentiation, but in PV, the reduced pSTAT1 response removes the break on erythropoiesis, allowing enhanced erythropoiesis to occur.

The role of *JAK2V617F* in the underlying pathogenesis of PV has been extensively explored using either restricted fragment length polymorphism analysis or the presence of marker cytogenetic abnormalities in patients with MPNs. The percentage of granulocytes and platelets that are *JAK2V617F* positive is often lower than the percentage of granulocytes belonging to the malignant clone. In addition, these marker cytogenetic abnormalities may occur before or after the acquisition of *JAK2V617F*. Furthermore *JAK2V617F*-negative erythroid colonies have been cloned in vitro in the absence of the addition of EPO, a hallmark of PV, indicating the presence of an undefined molecular lesion that precedes the *JAK2V617* mutation.

Several investigators have reported families in which multiple members have MPNs, including PV, ET, PMF, and CML, and have analyzed the *JAK2V617F*, *MPL*, and *CALR* status of family members. In affected patients, the *JAK2V617F* mutation was the most commonly acquired followed by *CALR* exon 9 mutations, with no *MPL W515L/K* mutations being detected. Interestingly, in some families, both *JAK2V617F*-positive and -negative members with MPN were observed. A small number of relatives who were *JAK2V617F* negative and did not have a diagnosis of PV, ET, or PMF had hematopoietic cells that formed endogenous erythroid colonies in vitro. Disease evolution can be highly variable within families presenting with the same type of MPN. These results suggest that an as yet unidentified genetic event, either germ-line or somatic, might contribute to the pathogenesis of PV, ET, and PMF, regardless of *JAK2* mutational status, and that there may be "initiating events" that precede the acquisition of *JAK2V617F* in these disorders.

Evidence has accumulated from epidemiological and familial studies that indicate that common low-penetrance factors present in the general population contribute to the risk of developing an MPN and possibly to the phenotype of the particular MPN. There is a 5- to 7-fold increased risk of MPN acquisition in first-degree relatives of individuals with the disease, amounting to a familial risk greater than that observed in breast, prostate, and colorectal cancer. Genetic studies have identified a limited set of loci associated with MPN predisposition. The germ-line constitutive *JAK2* haplotype, called GGCC or 46/1, has been shown to be a susceptibility factor for the development of *JAK2V617F*-positive PV. The *JAK2* 46/1 haplotype is also weakly associated with exon 12 *JAK2* PV, *MPL W515* MPNs, as well as MPNs that lack *MPL* mutations. How this *JAK2* SNP promotes the development of *JAK2V617F* MPNs remains the subject of great speculation, but two hypotheses have been proposed: (1) hypermutability of the chromosome region facilitates the acquisition of somatic mutation; or (2) the *JAK2* SNP confers a selective proliferative advantage, the so-called *fertile ground hypothesis*. Germ-line polymorphisms in the *TERT* gene have also been reported to predispose to *JAK2V617F*-positive and -negative sporadic and familial MPNs. The predisposition was far stronger in familial than sporadic MPNs, suggesting that low-penetrance variants might be responsible for the familial clustering of MPNs. Two additional SNPs involving TERT and HBS1L/MYB have been shown to have a stronger association with MPN populations with *CALR* or *MPL* mutations that lacked *JAK2V617F*. Reduced expression of MYB has been linked to ET-like disease in several animal models. In *JAK2V617F*-positive individuals, the reduced MYB associated with the MYB SNP favored the development of an ET phenotype. In addition, polymorphisms of the glucocorticoid receptor have been associated with PV and PMF but not ET. Bao and coworkers have extensively examined germline MPN predisposition SNPs by using an integrative approach to map risk variants to target genes. Remarkably, 11 of the 15 genes identified affect HSC self-renewal and function, including *ZNF521*, *GATA2*, *MECOM*, *RUNX1*, *HMGA1*, *ATM*, *FOXO1*, *TET2*, *JAK2*, *SH2B3*. They have hypothesized that MPN risk alleles expand the baseline pool of HSCs, which increases the risk of any one HSC acquiring an MPN-specific driver mutation.[24]

In the MPNs, acquisition of mutations in either *TET2* or *JAK2* may occur first, but those patients that acquire *JAK2V617F* first are more likely to develop PV. The concept that the MPN phenotype is the consequence of the order of mutational acquisition was first proposed by Ortmann and coworkers. *JAK2* and *TET2* mutations each occurred first in 50% of patients. *JAK2V617F* homozygosity was not required for acquisition of a *TET2* mutation to occur. *JAK2V617F* first patients were more likely to present with PV, were younger, more sensitive to ruxolitinib treatment, and were more likely to suffer from a thrombotic event than those individuals who acquired a *TET2* mutation initially. These data indicate that the order of acquisition of mutations might influence the clinical phenotype of the resultant MPN. *TET2* mutations have been shown to result in expansion of the malignant clone in elderly persons with normal blood counts, and in murine studies, a double-mutant *TET2–JAK2* clone was out competed by its *TET2* single-mutant ancestor. In mice, expression of *JAK2 V617F* but not TET2 resulted in increased erythropoiesis. A *TET2*-inactivating mutation but not *JAK2V617F* leads to HSC expansion. The report by Ortmann and coworkers suggests that in patients who acquire TET2 first, TET2 single-mutant hematopoietic stem and progenitor cells expand but do not give rise to excess differentiated megakaryocytic and erythroid cells until a *JAK2* mutation is acquired. By contrast, in patients who acquire JAK2 first, *JAK2* single-mutant hematopoietic stem and progenitor cells generate increased numbers of megakaryocytic and erythroid cells, and stem cell numbers only expand after acquisition of a *TET2* mutation. This model is consistent with the earlier clinical presentation of patients who first acquire a *JAK2* mutation since they more rapidly generate excess megakaryocytic and erythroid cells. The initial *TET2* mutation may modify the epigenetic program of HSCs and progenitor cells, and thus alter the consequences of the second mutation. A prior mutation of *TET2* alters the transcriptional consequences of *JAK2 V617F* in a cell-intrinsic manner and prevents *JAK2 V617F* from upregulating stem and progenitor cell proliferation.

The *JAK2V617F* Mutation Is Present in Hematopoietic Stem Cells in Polycythemia Vera

Previous studies had demonstrated that the majority of patients with PV had clonal involvement of multiple lineages, including myeloid, erythroid, and lymphoid cells. These results suggested that PV originates in HSCs with the ability to differentiate into multiple lineages. In addition, LOH at 9p24, known to correspond to homozygous *JAK2V617F* mutations, can be identified in both myeloid and lymphoid cells in some patients with PV, further suggesting that the underlying mutations occur in progenitor cells with the ability to differentiate into multiple hematopoietic lineages.

The *JAK2V617F* mutation has been detected in hematopoietic colony-forming cells and more mature progeny, such as neutrophils and platelets. Populations of cells enriched for HSCs, common myeloid progenitors (CMPs), granulocyte–macrophage progenitors (GMPs), and megakaryocytic–erythroid progenitors (MEPs) from patients with PV have been analyzed for the presence of the *JAK2V617F* mutation. *JAK2V617F* was detected in HSCs, CMPs, GMPs, and MEPs from patients with PV, supporting that PV is a disorder that arises in HSCs and involves the myeloid, erythroid, and megakaryocytic lineages. These data indicate that *JAK2V617F* in PV originates in lymphomyeloid progenitor cells. Analyses of hematopoietic cells from PV patients has suggested that *JAK2V617F* amplifies the terminal stages of hematopoiesis but not the more primitive hematopoietic stem/progenitor cells. In mouse models, however, *JAK2V617F* has been shown to lead to the amplification of both stem and progenitor cells, providing them with a competitive advantage compared with their normal counterpart through increased cell cycling and a reduced rate of apoptosis resulting in the emergence of the MPN phenotype. *JAK2V617F* may give only a subtle advantage, which will require several years for mutated stem and progenitor cells to predominate in humans over their normal counterparts. In man, other mutations such as *ASXL1*, *DNMT3A*, and *TET2* may further alter the biology of the *JAK2V617F*-mutated clone in a manner that affects phenotype as well as disease evolution.

Structural and Functional Aspects of *JAK2V617F*-Mediated Transformation

The *JAK2V617F* mutation occurs within the JH2 domain of JAK2, which has significant homology to the kinase domain of JAK2 (JH1) but lacks catalytic activity (see Fig. 70.5). The JH2 domain exerts an inhibitory effect on JAK2 kinase activity, and the *V617F* mutation is predicted to disrupt this inhibition. In vitro kinase assays with *JAK2V617F* and WT *JAK2* have revealed that *JAK2V617F* has greatly increased kinase activity, as assessed by autophosphorylation and by substrate phosphorylation. Ectopic expression of *JAK2V617F* in either epithelial or hematopoietic cell lines results in autophosphorylation of mutant *JAK2*, but not the WT *JAK2*, and activation of downstream signaling events. BAF3 or FDCP cell lines expressing the EPOR and engineered to stably express *JAK2V617F* are largely independent of the addition of exogenous growth factors and are hypersensitive to EPO. Coexpression of *JAK2V617F* and a homodimeric type 1 cytokine receptor (EPOR, TPOR, or G-CSFR) facilitates the transformation of cells to growth factor independence, suggesting that the mutant *JAK2* requires a receptor scaffold to be active. This contrasts with the effects of the *TEL-JAK2* fusion gene, which can readily transform cells on its own, presumably because of the strong homodimerization effects of the TEL moiety. Ectopic expression of *JAK2V617F* can also sensitize cells to the effects of IGF1, a characteristic feature of PV progenitors.

Expression of *JAK2V617F* in hematopoietic cells activates intracellular signaling pathways downstream of the EPOR, including STAT5, STAT3, the MAP kinase pathway, and the PI3K–Akt pathway. STAT5 is normally phosphorylated by the cytokine receptor–JAK2 complex, and phosphorylated STAT5 then translocates to the nucleus and activates the transcription of target genes. The target genes of STAT5 include Bcl-X_L, an important antiapoptotic protein known to be expressed in increased levels in PV proerythroblasts. The possibility that STAT5-mediated activation of Bcl-X_L is important in the pathogenesis of PV was suggested by observations that expression of either constitutively active STAT-5 or Bcl-X_L resulted in spontaneous erythroid colony formation. Furthermore, the degree of apoptosis can also be altered by TP53 levels. *JAK2V617F* appears to functionally inactivate TP53 by upregulating MDM2, an E3 ubiquitin ligase, thereby decreasing the degree of apoptosis. Preclinical studies have shown that MDM2 is overexpressed in PV stem/progenitor cells. In addition, cells expressing *JAK2V617F* display constitutive activation of the MAP kinase pathway (as assessed by phosphorylation of ERK), and of the PI3K pathway (as assessed by phosphorylation of AKT).

Furthermore, JAK2 has been shown to play a role in cellular MPL trafficking. Decreased expression of MPL on the cell surface of platelets and megakaryocytes is an established feature of PV and MF which leads to increased TPO levels. Lower expression of MPL on the cell surface of platelets and Mks in MPNs has been reported to be due to both a reduction in the recycling and maturation of the receptor as well as an increase in MPL proteasomal degradation mediated by *JAK2V617F* protein. Spivak and Moliterno and their group have performed seminal studies that indicate that the MPL/TPO axis plays a pivotal role in the biogenesis of PV. They have shown that MPL expression by HSCs is also reduced due to abnormal post-translational glycosylation. They have hypothesized that MPL processing plays a pivotal role in the biology of MPNs since MPL is the only hematopoietic growth factor receptor expressed by HSCs. To prove this they genetically manipulated MPL expression and maturation in a transgenic mouse model of PV. Elimination of MPL expression completely eliminated the development of PV phenotype, which was partially restored by expression of one MPL allele. Most importantly, elimination of TPO expression also eliminated the PV phenotype in this mouse model, and the PV phenotype could be restored with expression of a single TPO allele. These data indicate that PV is in part a TPO-dependent malignancy and that therapeutic strategies targeting the MPL-TPO axis should be evaluated in the future for the treatment of PV patients.[25]

Many PV patients have a low burden of *JAK2V617F*, as assessed by DNA sequencing, suggesting that there is either a subpopulation of cells that are homozygous for *JAK2V617F* mixed with WT cells or a clonal population of cells with one WT copy of *JAK2* and one mutant copy of *JAK2*. In PV, data from clonality or quantitative *JAK2V617F* assessment and from colony assays suggest that most PV patients have a subpopulation of cells homozygous for *JAK2V617F*, but in ET, clonal progenitor cells are heterozygous for *JAK2V617F*. The *JAK2V617VF* mutation occurs in a homozygous state in 25% to 30% of PV patients.[26] PV patients who are heterozygous for *JAK2V617F* have more mutated, committed progenitors than other PV patients, suggesting a selective amplification of mutated cells during the early phases of hematopoiesis. Dupont and coworkers have also demonstrated that mutated erythroid progenitors were more sensitive to EPO than normal progenitors, and that most *JAK2V617F* homozygous erythroid progenitors are actually EPO independent. The presence of *JAK2V617F* heterozygosity and homozygosity influences the clinical phenotype of PV patients. Vannucchi and coworkers have shown after a retrospective clinical analysis of a large number of PV patients that *JAK2V617F* homozygous patients were older, displayed a higher leukocyte count and hematocrit levels at diagnosis, and had larger spleens. Aquagenic pruritus was also more common in *JAK2V617F* homozygous PV patients. Furthermore, *JAK2V617VF* homozygosity was associated with more frequent evolution into PV related MF.[27]

Additional Mutations Associated With Polycythemia Vera

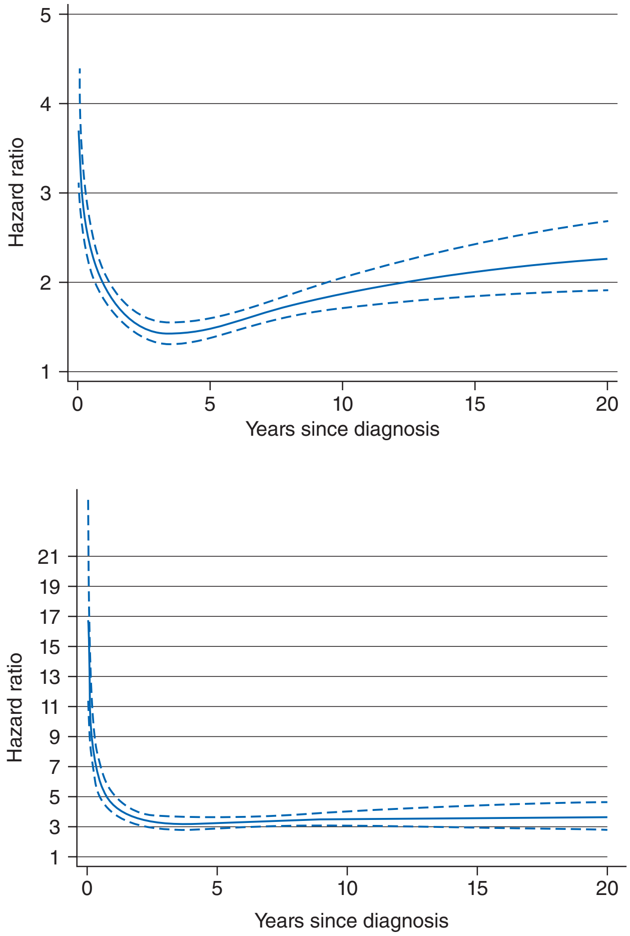
After the application of whole-genome assays (comparative genomic hybridization and SNPs) as well as whole-genome sequencing, an increasing number of mutations have been observed in patients with Philadelphia chromosome-negative MPNs. These mutations are not unique to any of the MPNs and are associated with AML and MDS. Four of these genes—*EZH2*, *ASXL*, *DNMT3a*, and *TET2*—participate in the epigenetic control of transcription and are discussed in greater detail in Chapter 59. *EZH2* mutations occur in 3% of PV patients, 7% to 16% of PV patients have *TET2* mutations, and 5% to 7% have mutations of *DNMT3a*; *ASXL* mutations are rare in PV (<7%). Each of these mutations may precede *JAK2V617F*, but the converse may also occur. Each of these mutations are far less frequent in PV and ET than PMF, supporting that these events may combine to generate a more accelerated phase of the classic MPN that phenotypically presents as MF. In addition to epigenetic regulators, mutations in genes that encode proteins that participate in the process of splicing immature mRNA have also been described in MPNs, specifically SF3B1, SRSF2, and U2AF1. *SF3B1* mutations are mostly found in PMF where they cluster within exons 12 to 16. Alterations in SRSF2 are mostly found in PMF and MPN evolved to AML. *U2AF1* mutations are detected in up to 15% of PMF cases, but are not present in ET or PV patients. *IDH1/2*, *IKZF* deletions, *NRAS/KRAS*, *p53* mutations, and *RUNX1* mutations rarely occur in PV but are all associated with transformation of an underlying MPN such as PV to MPN-BP.

The Hypercoagulable State That Characterizes Polycythemia Vera

Thrombosis is a major cause of morbidity and mortality in PV patients. These thrombotic events are most frequently microcirculatory and arterial, but venous thromboses are also of important clinical significance. In a population-based study from Sweden, Hultcrantz reported that the rate of arterial and venous thrombosis was significantly higher in patients with MPNs than in the general Swedish population. They demonstrated that the rate of thrombosis was significantly elevated in patients with MPNs across all age groups The absolute number of first arterial events was greater than the number of venous thrombotic events. The highest rate ratios for arterial and venous thrombosis were observed shortly after MPN diagnosis (3.0 and 9.7 respectively). The risk decreased during follow-up but continued to be elevated (Fig. 70.7).[28] The increased risk for thrombosis can be attributed to abnormalities in the vessel wall, blood cell components, a chronic inflammatory state, and the dynamics of blood flow. A number of risk factors for thrombosis have been investigated, but most of them are not firmly established.

In the European Collaboration on Low-Dose Aspirin in Polycythemia Vera (ECLAP) study, the incidence of cardiovascular complications was higher in patients older than 65 years (5.0% of patients per year; hazard ratio [HR]: 2.0; 95% confidence interval [CI]: 1.22 to 3.29; $P < .006$) or with a history of thrombosis (4.93% of patients per year; HR: 1.96; 95% CI: 1.29 to 2.97; $P = .0017$). Patients both with a history of thrombosis and older than 65 years had the highest risk of developing additional cardiovascular events (10.9% of patients per year; HR: 4.35; 95% CI: 2.95 to 6.41; $P < .0001$).[29] These data confirm previous findings that increasing age and history of thrombosis are the two most important prognostic factors for the development of vascular complications.

This information does not negate the increased incidence of thrombotic incidents also observed in younger patients with this disorder. In a series of 58 PV patients younger than 40 years of age, a disturbingly high incidence of life-threatening thrombotic events was observed. In fact, seven of the 10 patients in this series who died during the period of observation died from thrombotic events—four from Budd–Chiari syndrome (BCS), one from a pulmonary embolism, and two from cerebral thrombosis. Therefore, although a significant factor, preexisting atherosclerotic disease is not the sole etiologic factor in the genesis of thrombosis in PV. Analysis of the ECLAP study identified smoking in addition to older age as an important risk factor for major thrombosis. A retrospective study of 450 patients with PV demonstrated that hypertension and tobacco use were associated



Note: The beginning of the curve has been cropped to better visualize the hazard ratio during follow-up

Figure 70.7 Arterial (*top*) and venous (*bottom*) thrombosis during follow-up in patients with myeloproliferative neoplasms versus matched control participants. *(From Hultcrantz M, Björkholm M, Dickman PW, et al. Risk for arterial and venous thrombosis in patients with myeloproliferative neoplasms: a population-based cohort study. Ann Intern Med. 2018;168[5]:317–325.)*

with arterial thrombosis ($P < .02$) and diabetes mellitus was associated with venous thrombosis (P=.002).

The principal hemorheologic abnormality in PV is an elevated whole blood viscosity. The blood viscosity in PV is higher than that of normal control participants at all shear rates. In a retrospective analysis of PV patients with histories of vascular thrombosis, a strong correlation in univariate analysis between hematocrit level and the development of thrombotic episodes, including many cerebrovascular occlusions, was demonstrated. Cerebral blood flow is reduced in patients with PV in whom the hematocrit level is 53% to 62%. These abnormalities were observed even in patients with hematocrits at the lower levels, that is, 46% to 52%. Reductions in cerebral blood flow are correctable with phlebotomy. Reduction of the hematocrit by relatively small amounts frequently led to substantial improvements in whole blood viscosity and cerebral blood flow. Some PV patients apparently still maintain a higher-than-normal whole blood viscosity despite the normalization of the hematocrit, suggesting that an increase in hematocrit may not be the only factor responsible for increased blood viscosity. There appear to be important gender differences as related to the location of thromboses in PV patients. Women appear to have a higher incidence of thromboses within the abdominal cavity involving the portal, mesenteric, or hepatic vessels but a comparable rate of other vascular complications. Several groups have reported that patients with SVT frequently have endothelial cells that are affected by *JAK2V617F*, suggesting that in such individuals, their MPN might originate not at the level of the HSC but rather at the level of a hemangioblast, from which myeloid and endothelial cells originate. Such JAK2V61F-positive endothelial cells have been shown to exhibit a high efficiency of adhering to normal mononuclear cells, thereby likely leading to an increased risk of thrombosis.

A number of possible explanations have been suggested for the observed relationship between hematocrit level and the development of thrombotic events in PV patients. Platelet adhesion and thrombus formation on the vascular subendothelium are determined in part by the rate at which platelets are transported to the vascular surface. In a polycythemic condition in which increased numbers of RBCs are present, a greater number of intercellular collisions between RBCs and platelets occurs. These collisions could lead to increased platelet movement in a direction perpendicular to blood flow. This facilitation of platelet transport to the vessel wall may be an important factor in the development of thrombosis. An alternative explanation for the association between hematocrit level and the risk of thrombosis is based on the knowledge that blood viscosity is particularly sensitive to hematocrit levels. Increased hematocrits lead to increased blood viscosity, in turn leading to increased peripheral vascular resistance and an actual reduction in blood flow to a variety of organs, predisposing them to the development of thrombosis. The issue of hematocrits and thrombosis in PV has been prospectively investigated in an analysis of 1638 patients enrolled in the ECLAP study. In this prospective study, despite recommendations of maintaining hematocrit levels lower than 45%, only 50% of patients achieved this target during the follow-up, and 10% had hematocrit levels above 50%. These different hematocrit values were not associated with different thrombotic outcomes as assessed using univariate and multivariable analysis. However, in a recent prospective randomized clinical trial of 365 patients with PV, it was shown that patients with hematocrit maintained at less than 45% had a lower incidence of cardiovascular events compared with patients whose hematocrits were maintained at 45% to 50% (4.4% vs. 10.9%; $P = .02$). The group with lower hematocrit also had lower death rates from cardiovascular events or major thrombosis.[30] This study confirmed the need for strict hematocrit control in PV patients.

Additional factors have been implicated in the development of thrombosis in PV patients. Almost all patients with PV are iron-deficient. RBC size is a major determinant of platelet adherence, with larger RBCs leading to increased platelet adherence and smaller RBCs to decreased platelet adherence. Whether the increased membrane stiffness associated with iron deficiency is counterbalanced by the decreased platelet adherence associated with smaller RBCs is yet to be determined.

Inflammation may be another predictor of thrombosis in patients with PV.[21] In a retrospective study patients with increased inflammation as evidenced by an increased C-reactive protein (CRP) had significantly greater risk for thrombosis based on a multivariant analysis that adjusted for age, sex, ET, or PV diagnosis, cardiovascular risk factors, and *JAK2V617F* mutation status. Elevated circulating levels of pro-inflammatory cytokines generated by MPN cells and stromal cells in their microenvironment create a chronic systemic pro-inflammatory state potentially creating a pro-thrombotic environment. Conversely, inflammatory states may predispose to acquiring JAK2V617F and other MPN driver mutation and their clonal evolution.[31] CH and systemic inflammation are both linked to aging and risk of thrombosis. CHIP is a presence of a mutation known to occur in hematologic malignancies at relatively low allele frequency but without any clinically evident hematologic neoplasm. Patients with CHIP are at high risk of developing a true hematologic neoplasm such as MPN over time. CHIP has been shown to be associated with increased risk of coronary artery disease (CAD) and stroke. In an elderly population with known CAD, higher levels of high-sensitivity CRP were found to be present in those patients with CH again supporting the relationship between CH and inflammation (Fig. 70.8).

Thrombocytosis and qualitative platelet abnormalities occur frequently and are likely to be important contributory factors to the development of thrombosis. Some investigators have implicated uncontrolled thrombocytosis as a cause of thrombosis in these patients, but this relationship has not been confirmed by others. Increased plasma and urinary thromboxane production has been linked to increased platelet activation in these patients. A low-dose aspirin regimen selective for inhibition of platelet cyclooxygenase has been found to suppress increased thromboxane production in vivo and to clinically benefit patients with PV. Furthermore, elevated levels of serum VEGF and plasma TPO have been observed in patients with PV. These growth factors have been shown to lead to platelet activation.

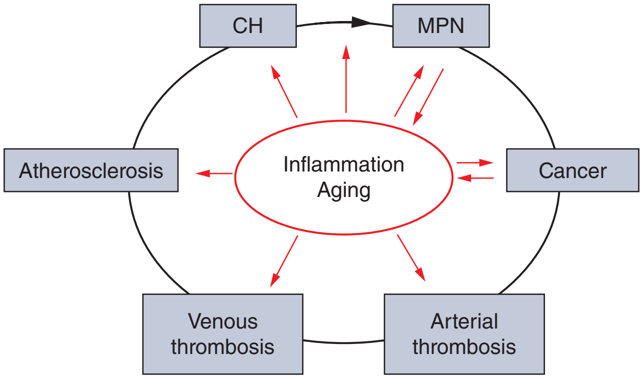


Figure 70.8 The relationship between inflammation and aging as risk factors (*red arrow*) for the development of CH, MPN, cancer, thrombosis, and atherosclerosis. *CH*, Clonal hematopoiesis; *MPN*, myeloproliferative neoplasm. *(From Moliterno AR, Ginzburg YZ, Hoffman R. Clinical insights into the origins of thrombosis in myeloproliferative neoplasms. Blood. 2021;137[9]:1145–1153.)*

Despite conflicting data, no clear clinical relationship between platelet number or function and the incidence of hemorrhage or thrombosis in PV patients has been delineated. An argument in favor of a role of elevated platelet numbers in the genesis of thrombosis in PV and ET is the observation in patients with ET that a reduction of excessive platelet numbers with the use of HU is associated with a reduction in the risk of developing thrombotic events. However, this should not be taken as evidence that the reduction in developing additional vascular events was caused by platelet count normalization alone; very likely, it may be related to the suppression by HU of each of three myeloid lineages. In line with this interpretation are the results of a randomized study performed by the Medical Research Council in the United Kingdom (PT-01) in which patients with ET were randomized to receive either HU or anagrelide therapy. This study showed that HU therapy rather than anagrelide, a selective platelet number-reducing drug, was associated with a reduction in the number of arterial thrombotic events, especially in *JAK2V617F* patients. In this study the rate of thrombosis in ET patients during follow-up did not vary according to different platelet numbers. Select patients with PV have, however, been afforded prompt resolution of vascular complications such as erythromelalgia or TIAs after institution of platelet antiaggregating agents or cytoreduction. It is important to emphasize that erythromelalgia does not resolve in PV patients with phlebotomy alone or with anticoagulation, but requires the use of platelet antiaggregating agents or reduction of platelet numbers. What distinguishes the clinical courses of these patients from those of others is unknown. These reports, coupled with the knowledge of abnormal thromboxane metabolism of platelets in PV, provide substance to the belief that platelets contribute to the generation of the thrombotic and hemorrhagic tendencies observed in PV. Although a number of clinical assessments of platelet function have been used to identify patients who are potentially at a high risk of developing a life-threatening hemorrhagic or thrombotic event, the results of these studies to date have been very disappointing. It appears that the etiology of thrombosis and hemorrhage in PV is multifactorial, and that the available tools are inadequate to identify patients at highest risk.

An elevation of WBC number occurs in 50% to 60% of PV patients, which may also have a detrimental effect on the rheology of the microcirculation in PV. An analysis of the ECLAP database showed that a baseline WBC count above $15{,}000 \times 10^6\,L^{-1}$ was associated with the development of major arterial events, mainly myocardial infarction. A retrospective study of 459 patients with PV showed a significant association between baseline leukocyte count greater than $15 \times 10^9/L$ and venous thrombotic events during a median follow-up of 64 months. Similar results were shown in two additional studies in patients with ET. On the other hand, a recent retrospective study of 520 PV patients seen at 10 academic institutions across the United States used group-based trajectory modeling and demonstrated that persistently elevated leukocyte trajectories were not associated with the hazard of a thrombotic event, but were actually significantly associated with increased hazard of disease evolution.[32]

Activated leukocytes may release proteases and oxygen radicals that alter endothelial cells and platelets so as to favor the development of a prothrombotic state. A series of markers of leukocyte activation, including expression of membrane CD11b and leukocyte alkaline phosphatase antigen, cellular elastase content, plasma elastase levels, and myeloperoxidase levels, are elevated in patients with PV. Limited and conflicting data are available as to whether or not there is a correlation between the presence of platelet–leukocyte interactions and thrombotic events. Increased expression of leukocyte adhesion molecules increases the adhesion of leukocytes to platelets and the endothelium. These cell-to-cell interactions stimulate the activation of endothelial cells and platelets, and induce the release from activated leukocytes reactive oxygen species as well as proteases that are capable of impairing a number of hemostatic processes. Platelet–leukocyte aggregates are increased in number in PV and are associated with an increased propensity to thrombose. In patients with PV and ET, increased levels of soluble plasma selectins were observed as compared to controls. In addition, platelets and vascular endothelial cells produce pro-coagulant microparticles. In a study of MPN patients microparticles were found to be significantly increased compared to controls. Furthermore, the increase was higher in patients with MPNs who had thrombosis. A recent study performed unbiased RNA sequencing in granulocytes and platelets of PV patients and found that expression of several thrombotic, inflammatory, and HIF-regulated genes is increased in these cells of PV patients.[33]

JAK2V617F allele burden has also been implicated as a potential risk factor for thrombosis. In a prospective study of 173 patients with PV that were followed for a median of 24 months, patients with a *JAK2V617F* allele burden of greater than 75% had a sevenfold increased risk of thrombosis compared with patients with an allele burden of less than 25%. However, another prospective study comparing patients with an allele burden of less than 50% versus less than 50% did not confirm the association between *JAK2V617F* allele burden and thrombotic risk. In a retrospective study of 186 patients with MPN, individuals harboring the *JAK2V617F* mutation were at highest risk for VTE. *JAK2* allele burdens higher than 20% identified patients with a sevenfold increased risk of VTE but not arterial thrombosis. In a recent retrospective study of 1537 MPN patients in China, of which 931 patients had PV, a multivariate analysis indicated that JAK2V617F allele burden greater than 50% was one of the risk factors for thrombotic events.[34] More studies are needed to clearly establish higher *JAK2V617F* allele burden as a risk factor for thrombosis.

Clearly, the thrombotic tendencies in PV are multifactorial and in the future it is likely that the thrombotic risk will be assessed on an individual basis, taking into account many of the factors mentioned previously.

Polycythemia Vera and the Risk of Hemorrhage

Patients with PV are also at an increased risk of developing minor as well as life-threatening hemorrhagic complications. The median incidence of all bleeding events and major bleeding events was reported in PV patients after a meta-analysis by Nicol et al. to be 6.5 and 1.0% patients/year respectively. Bleeding events occurred less frequently than thrombotic events and occurred at a similar incidence throughout the course of the disease. These bleeding events involved most commonly the gastrointestinal tract, skin, and occasionally the central nervous system. Bleeds within the central nervous system were the causes of death due to bleeding. Bleeding after surgery or trauma can also lead to significant morbidity and mortality. Abnormalities in platelet function and number have been implicated as the cause of this hemorrhagic tendency. Qualitative platelet abnormalities frequently found in these patients include platelet hypofunction, as demonstrated by defective in vitro platelet aggregation, acquired storage pool disease, and platelet membrane defects, and increased platelet reactivity, as demonstrated by enhanced platelet aggregation, increased plasma β-thromboglobulin levels, and shortened platelet survival. With platelet counts greater than 1000 to 1500 × 10^9 L^{-1}, the development of acquired von Willebrand syndrome is common (incidence of 49%) and can be associated with life-threatening hemorrhagic episodes. The use of anticoagulants or platelet function antagonists frequently contribute to the development of bleeding events especially in patients with acquired von Willebrand syndrome.[35]

Post-Polycythemia Vera Myelofibrosis and MPN-BP

A major cause of morbidity and mortality in PV results from the transition from the polycythemic phase of the disease to post-PV MF and/or to MPN-BP. These events usually occur a decade or more after the initial diagnosis of PV is made. Among a large cohort of 267 patients with PV, 12.5% to 21.0% of PV progressed to PV-related MF while MPN-PB has been estimated to occur in 6.8% of PV patients.[36] The PV patients who are at the highest risk of developing post PV MF and MPN-BP, in addition to their driver mutations frequently have additional malignancy mutations including TP53 and genes encoding chromatin (*IDH1/2, ASXL1, EZH2*) and spliceosome regulators (*SRSF2,U2AF1, SF3B1* and *ZRSR2*), transcriptional regulators (RUNX1 and NRAS) as well as homozygosity for *JAK2V617F*. Although *TET2* gene mutations are the most frequent non-driver mutations encountered in PV patients, they are not predictive of disease evolution. Also those patients with multiple complex cytogenetic abnormalities including loss of 17p which results in loss of TP53, multiple copies of 1q, and deletion of chromosome 7 also are at risk of having their PV progress to post PV MF or MPN-BP. The hematopoietic cells from patients destined to develop post PV MF and/or MPN-BP produce a number of cytokines that create a pro-inflammatory microenvironment within the BM and spleen which favors disease progression. In PVs, the fibroblastic component of the BM has been shown not to be directly involved in the malignant process but to react to the neoplastic clone by creating a tumor-promoting microenvironment. Several investigators have suggested that the release of growth factors, particularly VEGF, fibroblast growth factor, transforming growth factor-β, lipocalin, interleukin-6, interleukin-8, and tumor necrosis factor-α from myeloid cells are responsible for the marrow fibroblastic proliferation, increased marrow microvessel density, osteosclerosis, as well as the systemic symptoms observed in patients with PV-related MF. Whether the use of any particular therapeutic agents for treatment of PV accelerates the development of PV-related MF remains hotly debated, although it is well established that the use of alkylating agents such as pipobroman or chlorambucil increases the risk of developing acute leukemia. It remains a source of debate if treatment with HU increases the risk of developing MF or AML. The bulk of evidence does not support a clear leukemogenic role for this drug that is the standard of care for high-risk PV patients. Nevertheless, as a cautionary principle, it is wise to consider carefully the use of this agent in very young patients, in those carrying cytogenetic abnormalities, and in patients previously exposed to alkylating agents. In a report in which patients were treated exclusively with HU with an average follow-up of 16.3 years, the cumulative incidence of MPN-BP/MDS was 7.3%, 10.7%, and 16.6% at 10, 15, and 20 years, respectively, and was significantly lower than in patients treated with the alkylating agent pipobroman. However, patients treated with HU had a greater chance of developing MF (at 20 years, 31.6% vs. 21.3%). Whether HU really is leukemogenic is difficult to say from this study. The most likely possibility is that these rates of evolution reported with HU use merely reflect the natural history of the disease.

Post-PV MF is characterized by cytopenias, marrow fibrosis, an increasing burden of systemic symptoms, and extramedullary hematopoiesis. MPN BP can be preceded by an accelerated phase which is characterized by the appearance of 10% to 19% blasts in the peripheral blood which evolves to full blown BP when the blast cell count exceeds 20%. The MPN-BP patients frequently experience increasing consequences of their progressively enlarging spleen and/or liver, thrombocytopenia, leukocytosis, increasing numbers of blast cells in the peripheral blood and/or marrow, and increasing systemic symptoms. In some patients the increasing blast cell numbers observed in the peripheral blood are surprisingly not accompanied by increasing blast cells in the marrow, indicating that the cellular origin of the MPN-BP likely occurs in an extramedullary site, most frequently the spleen. Genetic studies of paired samples before and after leukemic transformation have suggested there are at least two distinct routes for leukemic transformation that are operational. Some patients who present with a *JAK2V617F/MPL* mutation-positive MPN progress to *JAK2V617F/MPL* mutation-positive MPN-BP that is associated with the acquisition of additional genetic alterations. A second, more complex, route to MPN-BP from the original MPN has been described in which a *JAK2V617F/MPL* mutation-positive MPN is followed by *JAK2V617F/MPL* mutation-negative MPN-BP. Clonality studies using X-chromosome inactivation in females demonstrated that *JAK2V617F/MPL* mutation-positive MPN and *JAK2V617F/MPL* mutation-negative MPN-BP are clonally related, consistent with transformation of an antecedent, pre-*JAK2V617F/MPL* mutation mutant clone that can progress to MPN-BP. Patients with *JAK2V617F*-positive MPN who developed *JAK2V617F*-negative MPN-BP had a shorter time between the diagnosis of the original MPN and the development of MPN-BP (3 + 2 vs. 10 + 7 years, respectively) than patients with *JAK2V617F*-positive leukemias. SNP array analysis has shown that genomic alterations occur at an increased frequency during the period of blastic transformation and that no single gene or molecular pathway is sufficient to cause transformation. A surprising correlation has been observed between the phenotype of the preceding MPN and the *JAK2* mutational status of the leukemic blasts after transformation. In contrast to *JAK2* WT MPN-BP, evolution to *JAK2V617F*-positive leukemia is invariably preceded by a myelofibrotic transformation of ET/PV or *JAK2V617F*-positive PMF. Because of these observations, myelofibrotic transformation of ET or PV is thought by many to represent an accelerated phase of the initial MPN preceded by genetic changes that result in evolution to MF and eventually MPN-BP. *JAK2* WT MPN-BP, by contrast, usually arises in patients with chronic-phase PV or ET that do not undergo evolution to MF. Some have suggested that these leukemias are therapy related. The reversion from *JAK2V617F* to WT *JAK2* in these leukemias has been shown not to be caused by homologous recombination. Two models have been proposed to account for the clonal relationship between *JAK2* WT MPN-BP and its preceding MPN: (1) both the chronic MPN and the MPN-BP arise from a shared pre-*JAK2V617F* founder clone; and (2) the chronic MPN and the MPN-BP arise from two independent stem cells. It remains possible that each model is viable and operates in different individual patients. Mutations in *CALR*, *JAK2*, *TP53*, *IDH2*, and *ASXL1* are frequent events in MPN BP, while mutations in *NPM1*, cohesin complex members, *FLT3*, and *CEBPA*, which are common events in de novo AML, are rarely, if ever, observed in MPN-BP. These data provide genetic evidence that MPN-BP is a distinct disease from classical AML with a unique mutational profile and molecular pathogenesis and that lack of response to AML chemotherapy regimens reflects the divergent biology of MPN-BP. Important differences in the mutational spectrum of *JAK2V617F* and *JAK2*-WT in post-MPN AML have been observed. *TP53* mutations are frequent, co-occurring events in patients with *JAK2V617F* mutations but not in patients with *CALR* mutations. In patients with co-occurring *JAK2V617F* and *TP53* mutations, the *JAK2*/*TP53* mutant clone dominates, consistent with potent cooperativity in vivo and with a dominant role in inducing transformation from the chronic *JAK2V617F*-positive MPN to AML. By contrast, mutations in members of the RAS pathway, *SRSF2*, and in *ASXL1* were more common in *JAK2* WT MPN-BP, and these mutations often were present as subclonal disease alleles at the time of transformation, suggesting they are not rate limiting in the transformation from the chronic to MPN-BP.

CLINICAL MANIFESTATIONS

The initial clinical manifestations of PV can largely be attributed to the excessive production of cells belonging to each of the myeloid lineages affected by the malignant process, including RBCs, platelets, and WBCs. With the implementation of laboratory tests during annual physical examinations, increasing numbers of people are being diagnosed with PV before the symptoms related to this neoplastic process become apparent. Symptomatic patients with PV may present to a physician with a myriad of nonspecific complaints, including headaches, weakness, pruritus, dizziness, excessive sweating, visual disturbances, paresthesias, joint symptoms, abdominal distress, a thrombotic or hemorrhagic episode, and weight loss. Thrombosis is a frequent presenting event. Two-thirds of such thrombotic events occur either at presentation or before diagnosis and the remainder most often during the first 10 years of follow-up. At diagnosis, one-third of patients have already lost 10% of their body weight, presumably secondary to the hypermetabolism associated with this disorder, and complaints of fatigue are common. Arthropathies are frequently observed and are largely caused by the clinical manifestations of gout. The hyperproliferative BM state characteristic of PV and the increased nucleoprotein degradation are contributory factors in the development of hyperuricemia.

The principal findings on physical examination of a patient with PV include ruddy cyanosis, conjunctival plethora, hepatomegaly, splenomegaly, and hypertension. Untreated patients are at particularly high risk for thrombotic and hemorrhagic events. In several large series of patients with PV, thrombosis was the cause of death in 30% to 40% of patients. Arterial thrombotic events account for two-thirds of such events, with venous thrombotic events representing the remainder. Ischemic stroke, myocardial infarction, and TIAs are the most common arterial thrombotic events. Patients may also present with deep venous thrombosis in the lower extremities, pulmonary embolism, or peripheral vascular occlusions. The cumulative rate of thrombosis ranges from 2.5% to 5% per patient per year. The prevalence of thrombosis at diagnosis ranges from 34% to 39%. It is not unusual for patients with PV to develop thromboses at unusual anatomic sites; in particular, thromboses are relatively frequent in the splanchnic veins, including the splenic, hepatic, portal, and mesenteric vessels or cerebral sinus veins, thrombosis of the vena cava, and intraventricular thrombosis. A particularly serious thrombotic event associated with PV is BCS, which results from hepatic venous or inferior vena caval thrombosis and obstruction. These events lead to hepatic venous outflow obstruction, increased hepatic sinusoidal pressure, and portal hypertension. Portal venous perfusion of the liver is frequently reduced, leading to portal venous thrombosis and hypoxic damage of liver parenchymal cells. This cascade of events results in centrilobular hepatic necrosis, centrilobular fibrosis, and nodular regenerative fibrosis, which culminates in the development of cirrhosis of the liver. The cause of BCS can be identified in 75% of cases, including hereditary and acquired prothrombotic disorders, trauma, and infection. PV account for 10% to 40% of all cases of BCS. Paroxysmal nocturnal hemoglobinuria is also a frequent cause of BCS (see Chapter 32). Because BM cells from 87% of patients with idiopathic BCS form erythroid colonies in the absence of EPO, such patients were in the past believed to have a forme fruste of an MPN. The identification of these latent MPNs, without elevated blood counts, has been facilitated by screening for *JAK2V617F*. These patients tend to be younger and female, and to have normal blood counts caused by hemodilution and hypersplenism, which mask an elevated RBC mass. Many of these patients (37%) also have another predisposing factor for thrombosis such as exposure to oral contraceptives, antiphospholipid antibodies, factor V Leiden, or protein C deficiency. The *JAK2V617F* mutation has been reported in 32.7% of 831 patients with an idiopathic splanchnic vein thrombosis. In another study, the mutation was present in 49% of patients at diagnosis of the idiopathic form of splanchnic vein thrombosis (SVT), of which 60% were diagnosed as having a coexisting MPN; more than 52% of the remaining patients went on to develop an MPN after a median of 49 months. *JAK2V617F* was detected in 45% of patients with BCS, and at least in one series, BCS is occasionally observed in PV patients with exon 12 *JAK2* mutations.[37]

Furthermore, additional patients (6.9%) who have idiopathic SVT have a BM histopathologic picture diagnostic of an MPN but are *JAK2V617F* negative. The diagnostic value of low serum EPO level in BCS has been questioned because elevated levels have been attributed in *JAK2V617F*-positive patients with necrotic liver tissue.

There are fulminant, acute, subacute, and chronic forms of BCS. These clinical manifestations depend on the extent and rapidity of hepatic vein occlusion and the development of venous collaterals to decompress the venous sinusoids. One should always consider a diagnosis of BCS in any patient with an MPN with ascites, upper abdominal pain, and liver function abnormalities. This syndrome is characterized by hepatosplenomegaly, ascites, edema of the peripheral extremities, and distension of superficial abdominal veins caused by resultant portal hypertension. Routine biochemical determinations of hepatocellular function and injury are frequently of little diagnostic value in patients with suspected BCS. Doppler ultrasonography is the best tool for screening patients for BCS. This test has a sensitivity and specificity of 85%. Characteristic findings include an absence of flow in the hepatic veins or nonvisualization of the hepatic vein. Contrast-enhanced computed tomography scanning and magnetic resonance imaging (MRI) are useful in better defining the hepatic venous anatomy. Hepatic venous and inferior vena caval catheterization is a key diagnostic procedure indicating the sites of venous obstruction. The diagnosis can be definitively made by a spider web pattern on hepatic venography. Transjugular liver biopsy specimens usually reveal intense congestion and cellular atrophy.

It has been emphasized that patients with PV can present with portal or hepatic vein thrombosis with normal hemoglobin or hematocrit values. Such patients may have leukocytosis, thrombocytosis, or splenomegaly. Screening for the *JAK2* mutation should be systematically carried out in such situations. Gastrointestinal bleeding or an increase in plasma volume that is a consequence of splenomegaly often accounts for the normal blood counts in such patients with BCS. The factors operational in the PV patient that lead to the development of hepatic vein thrombosis are believed to be multiple. Whereas splenomegaly causes increased portal blood flow, extramedullary hematopoiesis within the hepatic sinusoids frequently obstructs hepatic blood flow, and *JAK2V617F*-positive endothelial cells might affect adhesion to monocytes, leading to aggregation of blood elements. These processes are surely important contributory factors in addition to the other previously discussed risk factors that lead to the development of thrombosis in this patient population.

Neurologic abnormalities occur in almost 60% to 80% of untreated or poorly controlled PV patients and include TIAs, cerebral infarction, cerebral hemorrhage, fluctuating dementia, confusional states, and choreic syndromes. PV-associated chorea[59] (Video 70.1) has been reported as a presenting complaint, primarily in older females, which typically involves the orolingual or appendicular musculature and often resolves with phlebotomy or cytoreductive therapy. In addition, complaints of dizziness, paresthesias, visual disturbances, tinnitus, and headaches have been attributed to the increased blood viscosity and reduced cerebral blood flow caused by erythrocytosis. The transient neurologic symptoms can also be the consequence of small infarcts in the region of the basal ganglia, which can be detected by computed tomography. These small infarcts are known as *lacunae* and result from the occlusion of small penetrating arteries, which are particularly susceptible to thrombosis. Cerebrovascular thrombosis occurs more often in PV patients than in the general population. Symptoms caused by intermittent carotid or vertebral basilar artery insufficiency (or both) occur so frequently in PV that it is suggested that every patient with focal cerebrovascular insufficiency should at least have a complete blood count to exclude the diagnosis of an underlying MPN.

Thrombosis of the dural sinus or cerebral veins (CVT) is an uncommon form of stroke, usually affecting young individuals. CVT represents about 0.5% to 1% of all strokes. While 3.8% of CVT patients are diagnosed with MPNs, 0.4% of MPN patients have a CVT during their clinical course. Headache, generally indicative of an increase in intracranial pressure, is the most common symptom in CVT. Clinical manifestations of CVT may also depend on the location of the thrombosis. The superior sagittal sinus is most commonly involved, which may lead to headache, increased intracranial pressure, and papilledema. A motor deficit, sometimes with seizures, can also occur. Scalp edema and dilated scalp veins may be seen on examination. For lateral sinus thromboses, symptoms related to an underlying condition (middle-ear infection) may be noted, including constitutional symptoms, fever, and ear discharge. Pain in the ear or mastoid region and headache are typical. Hemianopia, contralateral weakness, and aphasia may sometimes be seen owing to cortical involvement. Approximately 16% of patients with CVT have thrombosis of the deep cerebral venous system (internal cerebral vein, vein of Galen, and straight sinus), which can lead to thalamic or basal ganglial infarction. Cavernous sinus thrombosis is usually associated with a primary infectious etiology involving a focus in the face, throat, mouth, ear, or sinuses. Aseptic cavernous sinus thrombosis is an extremely rare phenomenon that has been reported in patients with PV. These patients present with monocular blindness and the characteristic features of ipsilateral cavernous sinus thrombosis, and only retrospectively is the diagnosis of PV made. Therefore, patients found to have this symptom complex who have no known infectious predisposing causes should be carefully evaluated to rule out a diagnosis of PV. The most sensitive diagnostic technique is MRI in combination with magnetic resonance venography.

Thrombosis of large-caliber arteries is a relatively rare event in PV patients, but there have been case reports of thromboses within the chambers of the heart, leading to refractory congestive heart failure and acute aortic occlusion. Such catastrophic thrombotic events in the heart or large vessels would suggest that cardiac catheterization be performed with some caution.

PV frequently manifests with symptoms caused by peripheral vascular disease. In these cases, patients may first be seen by surgeons or dermatologists. Intense redness or cyanosis of the digits with or without burning, classic erythromelalgia, digital ischemia with palpable pulses, or thrombophlebitis without another known cause may be the presenting symptoms.

Erythromelalgia is characterized by burning pain in the digits, an objective sensation of increased temperature, and relief by cooling. PV is the most common cause of erythromelalgia and is one of the few disorders in which digital ischemia with or without ulceration may exist in the presence of palpable pulses. Other disorders that can lead to this abnormality include embolism, trauma, cutaneous infarction, neuritis, infection, and various types of arteritis. Painful and ulcerating toes and fingers have been observed to be presenting symptoms in patients with PV. The likelihood that arterial insufficiency is the cause of such ulceration is quite small in patients who have a palpable dorsalis pedis and posterior tibialis pulses; in this situation, the possibility of an underlying hematologic disorder such as PV should be entertained. Foot pain at rest is a distressing but not widely recognized symptom of PV. In patients with this complaint, peripheral pulses are of normal character, and cutaneous circulation appears to be adequate. The pain is most severe at night, is dull in nature, and occurs primarily in the feet or legs. These symptoms have been shown to be the results of platelet activation and aggregation in vivo, which preferentially occur in arterioles. If untreated, erythromelalgia can progress to ischemic acrocyanosis or gangrene. Phlebotomy alone in PV does not improve erythromelalgia. These symptoms can be abolished by reducing the platelet counts to normal levels and can be rapidly reversed after the institution of antiplatelet aggregation therapy but not anticoagulation. Therefore, the cause of erythromelalgia appears to be closely linked to abnormal arachidonic acid metabolism that occurs within PV platelets.

Retrospective reviews have revealed a higher-than-expected number of patients with PV and pulmonary artery hypertension. PV is associated with nearly a threefold higher risk for developing pulmonary artery hypertension.[38] This diagnosis usually requires transthoracic echocardiography followed by a right heart catheterization. Proposed etiologies include direct obstruction of pulmonary arteries by circulating megakaryocytes, extramedullary hematopoiesis in the pulmonary parenchyma, smooth muscle hyperplasia induced by release of PDGF from activated platelets, chronic disseminated intravascular coagulation, and unrecognized recurrent pulmonary emboli. The diagnosis of pulmonary hypertension is made, on average, 9.5 years after the diagnosis of the underlying MPN and is associated with a poor prognosis, with death usually occurring as a result of congestive heart failure or pneumonia. Although anecdotal reports have claimed improvements in patients' pulmonary artery pressure with control of the underlying disease, others have not found any change in serial measurements of 11 patients' pulmonary arterial pressures despite good disease control. Ruxolitinib therapy has been reported to result in improved outcomes, pulmonary and echocardiographic findings, as well as correction of cytokine dysregulation in MPN patients with pulmonary hypertension. Ironically, several case reports have linked ruxolitinib exposure to the development of pulmonary hypertension. The use of ruxolitinib in treating pulmonary hypertension remains uncertain and patients should be monitored carefully if it is used for these purposes

As many as 30% to 40% of patients with PV experience some sort of hemorrhagic event, which can be relatively trivial, such as epistaxis or gingival hemorrhage, or can be life-threatening, such as gastrointestinal hemorrhage or hematomas involving vital organs. The gastrointestinal tract is a frequent site of hemorrhagic complications because patients with PV are predisposed to portal vein thrombosis and resultant variceal bleeding and peptic ulcer disease. Gastroduodenal erosions and ulcers, and *Helicobacter pylori* infection are all significantly more common in PV patients than in control patients with dyspepsia. This may be partly attributable to altered mucosal blood flow as a result of increased plasma viscosity or increased histamine release caused by peripheral blood basophilia. Cerebral hemorrhage is a common cause of morbidity and mortality. Bleeding events frequently occur with the use of aspirin or other nonsteroidal antiinflammatory agents; an association between the hemorrhage and the use of high doses of these platelet-paralyzing drugs has been made in almost one-third of such instances. Low-dose aspirin therapy has, however, been reported not to lead to an increased incidence of life-threatening hemorrhagic events. Spontaneous bleeding in patients with PV is relatively rare, although spontaneous retropharyngeal hematomas leading to acute upper airway obstruction or hematomas in the groin or retroperitoneum have been reported.

Patients with PV who undergo surgical procedures are at a very high risk of developing postoperative complications. In one series of 62 major operations on 54 patients with PV, postoperative complications occurred in 49% of patients; 52% of complications were from hemorrhage, 18% from thrombosis, and 14% from hemorrhage and thrombosis. The postoperative mortality rate in this patient population was 18%. In another series of 15 patients, five had serious complications secondary to thrombosis and hemorrhage. A study by an Italian group retrospectively evaluated 311 surgical interventions in 105 patients with PV and 150 with ET: 24 arterial or venous thromboses (7.7%), 23 major hemorrhages (7.3%), and five surgery-related deaths (1.6%) were observed within 3 months of the procedure. PV patients with uncontrolled erythrocytosis before surgery have been shown to have the highest complication rate. Patients with inadequately controlled disease had a 79% incidence of complications, but in those with adequate hematologic control before surgery, the rate of perioperative and postoperative complications was reduced to 28%. In addition, the duration of disease control was an important factor in decreasing surgical risk; a prolonged period of effective disease control before surgery reduced the complication rate to 5%. Complication rates after surgery can therefore be dramatically reduced by appropriate therapeutic interventions with normalization of blood counts. The chief deterrent to such an approach has been the failure by physicians to recognize the risk associated with PV in the surgical setting.

Another situation that puts patients with PV and ET at high risk for thrombosis is pregnancy. Maternal and fetal complications have been reported. Specifically, the rate of fetal loss is higher than that of the general population.

Generalized pruritus occurs in approximately 40% of cases of PV. Water contact, such as during showers or bathing, induces attacks of intolerable pruritus. There appears to be no clear relationship between the degree of the pruritus and severity of the disease, and 20% of patients continue to experience itching despite reduction of their hematocrits to normal levels. Aquagenic pruritus is significantly more common among *JAK2V617F* homozygous patients than heterozygotes. The degree of pruritus is so severe in some patients that they are unable to tolerate bathing at all and find it necessary to substitute gentle skin swabbing or to simply not bathe. The etiology of the pruritus in PV remains uncertain. Several groups have attempted to implicate elevated blood and urine histamine levels in its pathobiology. A strong correlation between skin mast cell numbers and the severity of itching has been demonstrated, and mast cells in PV have been shown to be *JAK2V617F* positive. However, the failure of the pruritus to respond to antihistamine therapy in many patients suggests that abnormally high histamine levels probably do not constitute the sole factor in its development.

Iron deficiency has also been implicated as a factor contributing to pruritus in PV patients who are almost invariably iron-deficient. Iron-substitution therapy has resulted in symptomatic improvement, but this approach is less than optimal because it frequently results in uncontrollable erythrocytosis. One theoretical approach to combat this therapeutic challenge is to use hepcidin to correct iron deficiency in PV patients while restricting the iron available for erythropoiesis at the same time. A phase II study of hepcidin mimetic PTG 300 (rusfertide) is currently testing this hypothesis. Ruxolitinib therapy has been reported to be effective in alleviating the patient's aquagenic pruritis in 80% of patients.

The risk of development post-PV MF is increased with prolonged duration of disease and is directly related to the duration of long-term follow-up, but the influence of the modality used to treat the initial PV phase of the disease on the rate of transformation to this more accelerated form of the disease remains uncertain. Post-PV MF should be considered the natural evolution of PV. Criteria for the diagnosis of post-PV MF have been established (Table 70.2) and can be used as a guide for documenting this transition in disease phenotype, which in reality represents a point in the continuum of PV. For patients with disease duration greater than 10 years, the HR was 15.24 (95% CI: 4.22 to 55.06; $P < .0001$). The median interval between the diagnosis of PV and the development of post-PV MF is 13 years. Post-PV MF is characterized by (1) increasing splenomegaly; (2) teardrop RBC morphology; (3) extensive BM fibrosis; (4) a leukoerythroblastic blood picture, systemic symptoms including fatigue, weight loss, night sweats, bone pain, and fevers; and (5) anemia and or thrombocytopenia. The patients may be entirely asymptomatic but often complain of fatigue, dizziness, weight loss, and anorexia. Splenomegaly can lead to abdominal pain caused by repeated splenic infarcts and to early satiety caused by mechanical obstruction of the upper gastrointestinal tract. Patients with post-PV MF are virtually all *JAK2V617F* positive and characteristically have high *JAK2V617F* allele burdens.

The anemia that characterizes post-PV MF is primarily a result of splenic pooling, ineffective erythropoiesis, hemolysis, and extramedullary production of RBCs with a shortened RBC survival. Patients positive for *JAK2V617F* are less likely to require blood transfusions but have a poorer survival. Occasionally, the anemia is exacerbated by folate or iron deficiency. Before assuming that a patient has entered

TABLE 70.2 **International Working Group for Myelofibrosis Research and Recommended Treatment Criteria for Post-Polycythemia Vera Myelofibrosis**

Required Criteria

1. Documentation of a previous diagnosis of polycythemia vera as defined by the WHO criteria
2. Bone marrow fibrosis grade 2–3 (on 0–3 scale) or grade 3–4 (on 0–4 scale)

Additional Criteria (Two Are Required)

1. Anemia or sustained loss of requirement of either phlebotomy (in the absence of cytoreductive therapy) or cytoreductive treatment for erythrocytosis
2. A leukoerythroblastic peripheral blood picture
3. Increasing splenomegaly defined as either an increase in palpable splenomegaly of ≥5 cm (distance of the tip of the spleen from the left costal margin) or the appearance of a newly palpable splenomegaly
4. Development of ≥ one of three constitutional symptoms: >10% weight loss in 6 months, night sweats, unexplained fever (>37.5°C)

Adapted from Barosi G, Mesa RA, Thiele J, et al. Proposed criteria for the diagnosis of post-polycythemia vera and post-essential thrombocythemia myelofibrosis: a consensus statement from the international working group for myelofibrosis research and treatment. *Leukemia*. 2008;22:437.
WHO, World Health Organization.

post-PV MF, it is prudent to assess BM iron stores. Replacement therapy with iron may lead to the resurgence of erythropoiesis and prevent the faulty categorization of disease progression.

Bleeding abnormalities caused by thrombocytopenia or qualitative platelet abnormalities are especially common during this phase of the disease. Frequent instances of epistaxis or ecchymoses occur, and gastrointestinal hemorrhage caused by esophageal varices arising from portal hypertension is a recurrent problem. The majority of hemorrhagic events are minor in nature. Frequently, patients have generalized wasting characterized by progressive asthenia and weight loss. Severe hyperuricemia, leading to secondary gout or uric acid nephropathy, may also complicate the clinical course.

The median survival for patients with post-PV MF is 5.7 years. Patients with post-PV MF are at a high risk for the development of MPN-BP. Of patients who develop post-PV MF, approximately 18% will undergo leukemic transformation after 3 years and likely a greater number with longer follow-up.

The leukemic transformation of PV has been extensively described. The possibility that a relationship exists between the therapeutic modality used during the erythrocytotic phase and the frequency of development of MPN-BP has been a point of heated discussion. Some of the controversy surrounding this question was formerly caused by a lack of understanding of the basic origins of PV. Clinical hematologists in the 1950s and 1960s frequently thought of PV as a benign hematologic abnormality and believed that therapeutic interventions either with alkylating agents or radiotherapy were solely responsible for the development of MPN-BP. That concept has proved erroneous, and PV, similar to the other MPNs, has been shown to be a clonal malignant hematologic disorder. The evolution to MPN-BP can therefore be thought of as a natural consequence of this malignant disorder, which can be accentuated by the therapeutic interventions already discussed. In fact, 25% of patients who develop MPN-BP have never been exposed to any form of cytotoxic therapy.

Further insight into the relationship between MPN-BP and PV has been best provided by the results of the PV Study Group (PVSG), which described a randomized trial comparing the use of phlebotomy, chlorambucil, and ^{32}P for the treatment of this disorder. The incidence of MPN-BP was approximately 1.5% in patients treated with phlebotomy alone, 17.5% in patients treated with chlorambucil, and 10.9% in patients treated with ^{32}P after over 15 years of follow-up. The incidence of MPN-BP in the patients treated with phlebotomy alone is therefore much higher than that expected in a normal age-matched control group, again indicating that leukemia is a natural evolutionary event in the clinical course of an individual with PV. The incidence of MPN-BP can be increased, however, by the institution of therapy with either alkylating agents or ^{32}P. The time course for the development of MPN-BP appears to be dependent on the treatment used to control the polycythemia. The development of MPN-BP in patients treated with phlebotomy in the PVSG trial was limited to the first 5 years of treatment, suggesting that the development of MPN-BP is not solely attributable to the prolongation of survival. In contrast, analysis of the hazard function was virtually flat for patients treated with chlorambucil from years 2 to 7 after randomization; however, the risk for MPN-BP became alarmingly high after 10 years of study, suggesting that the risk of MPN-BP increases with time even after the drug has been stopped. One half of the cases of MPN-BP in the chlorambucil arm occurred during the first 5 years, with the remainder equally split between the second and third 5-year periods. In contrast, 60% of the cases of MPN-BP in the group treated with radioactive phosphorus occurred 6 to 10 years after randomization. Of particular concern is the high incidence of MPN-BP reported in patients who were initially treated with radioactive phosphorous or busulphan and then switched to maintenance therapy with HU, previously believed to be a nonleukemogenic agent. Some light was shed on the genetic basis of the early and delayed onset MPN-BP following PV by Paz and co-workers. They identified groups of PV associated with a distinct time to leukemic transformation. Transformation to MPN-BP after short-term follow-up was characterized by a complex molecular landscape with mutations in *IDH1/2*, *RUNX1*, and *U2AF1* genes occurring, while evolution to MPN-BP over longer periods of time was associated with mutations in *TP53*, *NRAS*, and *BCORL1* genes.[39] The association between *TP53* mutations and long-term transformation to MPN-BP is usually related to the necessary inactivation of the second allele of *TP53* for leukemic transformation either by a mutation in the other allele, deletion of 17p where the gene for TP53 is located or the acquisition over time of multiple copies of 1q in which MDMD4, a degrader of P53, is encoded. Also transcripts for MDM2, as well as the protease PPM1D, which also degrade P53 activity, are progressively upregulated in PV over time leading to further loss of P53 activity. Furthermore activating mutation of PPM1D can also contribute to this process. This progressive loss of P53 activity during the course of PV due to multiple genetic events has been proposed by Marcellino and coworkers to play a pivotal role in the development of MPN-BP (Fig. 70.9).[40] These mutations were frequently already present during the PV phase, either with a high VAF (short-term transformation) or with a low VAF (especially *TP53* mutations). These data suggest that the evolution of PV to MPN-BP may be driven by distinct time-dependent molecular and cytogenetic events. The use of a combination of an alkylating agent, busulphan, pipobroman, or melphalan, may particularly increase the risk of leukemia. Approximately 30% to 50% of patients with PV who develop MPN-BP have previously entered the post-PV MF phase. In contrast,

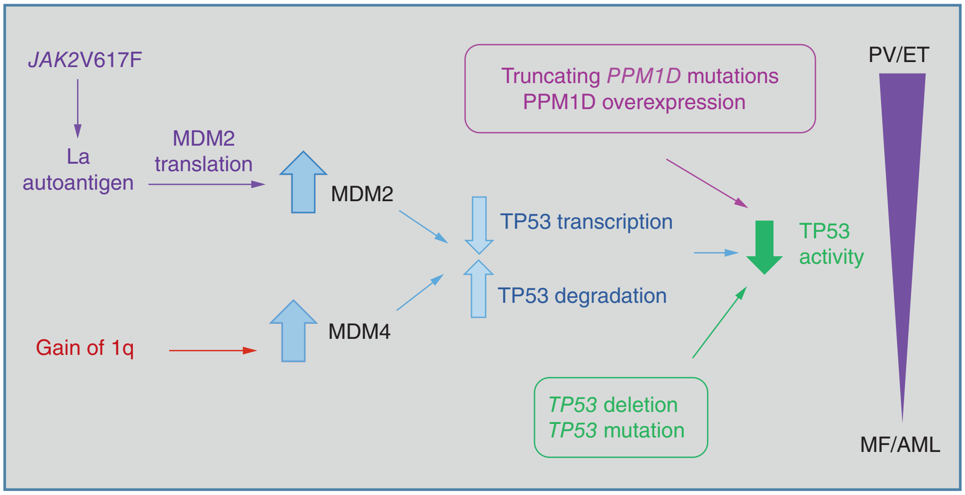

Figure 70.9 MULTIPLE MECHANISMS TO DOWNREGULATE TP53 ACTIVITY IN PV. *ET*, Essential thrombocythemia; *MF*, myelofibrosis; *PV*, polycythemia vera.

approximately 50% of patients progress directly from the erythrocytotic phase to MPN-BP. The phenotype of the leukemia cells that characterize the MPN-BP is overwhelmingly myeloid, although rare cases of lymphoblastic and biphenotypic leukemias have been reported. Patients with *JAK2V617F*-positive MPN are also at a higher risk of developing both additional hematologic malignancies and solid tumors. The SNPs for TERT, which is a susceptibility factor for familial and sporadic MPNS, have also been shown to be associated with a variety of solid tumors. The presence of this SNP predisposes to the development of MPNs and the co-occurrence of solid tumors, especially in patients receiving cytoreductive therapy. Some investigators have suggested that prolonged cytoreductive therapy be avoided in patients with the TERT polymorphism. In addition, low-grade lymphoproliferative disorders such as chronic lymphocytic leukemia and MGUS have been shown to coexist in patients with a variety of MPNs, including PV, and not to have an adverse effect on prognosis.

In some instances, a preleukemic phase characterized by refractory anemia with excess blasts has been described. In fact, half of such cases of MPN-BP in one series were preceded by a myelodysplastic disorder.

PV can be associated with unanticipated consequences. Johansson reported that in 10,752 patients diagnosed with an MPN in Sweden from 1995 to 2015 there was a significant increased risk of both hip and vertebral fracture for the total group of MPN-patients compared with the total Swedish population and this effect was especially noticeable in PV patients. The risk for hip fracture was increased in PV patients by 37% and the risk for vertebral fracture was increased by 109% in patients with PV. Studies of PV mouse models have provided some insights into this increased risk of bone fractures. PV mouse models are associated with decreased osteoblast activity in mice, and polycythemia due to chronically elevated EPO levels in mice also results in bone loss, and implications on patients treated with rEPO should be evaluated.[41]

LABORATORY MANIFESTATIONS

Laboratory evaluation of patients with erythrocytosis involves the careful use of a broad range of diagnostic studies. Because PV is a panmyelosis, the overwhelming number of patients has elevated hematocrits, WBC counts, and platelet counts. The diagnosis of PV has been greatly simplified by the discovery of the *JAK2V617F* mutation, which is present in more than 95% of PV patients. Hematocrit values greater than 49% in males and greater than 48% in females are abnormal and require further evaluation. Documentation of the absolute increase in RBC mass is rarely required and is a test that is available at few institutions. A hematocrit value greater than 60% in men or greater than 55% in women is almost always associated with an absolute erythrocytosis. Occasionally, an elevated RBC mass can actually be present in the face of a normal hematocrit value. In cases of splenomegaly caused by portal hypertension, an expanded plasma volume may mask an elevated RBC mass. In addition, iron deficiency can also lead to a normalization of the hematocrit in PV, making the diagnosis difficult. PV is associated with a 20% to 30% frequency of peptic ulcers and gastritis, which can be associated with blood loss. In this situation, thrombocytosis may be exacerbated as a consequence of the iron deficiency. Iron supplementation is not necessary to make a diagnosis of an MPN because of the availability of molecular diagnostic studies

Leukocytosis is present in approximately two-thirds of cases and seems to be proportional to the burden of *JAK2V617F*. Thrombocytosis is observed in 50% of cases. Abnormalities of RBC, WBC, and platelet morphology are frequently observed. The morphologic RBC changes observed during the erythrocytotic phases are characteristic of iron deficiency and include microcytosis, hypochromia, and frequently polychromatophilia. Some anisocytosis and poikilocytosis can be seen as well. Fetal hemoglobin levels and the number of RBCs containing fetal hemoglobin, known as *F cells*, may be increased. The WBCs are characterized by normal morphology, although the numbers of basophils, eosinophils, and immature myeloid forms can be increased. Platelet morphology is also quite striking in PV. Frequently, megathrombocytes (platelets the sizes of RBCs) are seen on the peripheral blood smear. Patients typically have platelet counts of less than $1 \times 10^6\,\text{mm}^{-3}$, but it is not unusual to observe a patient with a platelet count higher than this value. PV-related MF is characterized by a leukoerythroblastic blood picture, with the appearance in the peripheral blood of dacryocytes or teardrop RBCs, myelocytes, metamyelocytes, and (rarely) blasts and promyelocytes in addition to nucleated RBCs in the peripheral blood.

Platelet aggregation studies do not correlate frequently with the risk of bleeding episodes. The most common abnormalities are decreased primary and secondary aggregation to either or both epinephrine and adenosine diphosphate, and decreased response to collagen with generally a normal response to arachidonic acid. An abnormal platelet storage pool disease is a characteristic feature and is caused by abnormal platelet activation. Others have employed rotational thromboelastometry to screen for PV patients who are at an increased risk of developing bleeding or thrombotic events. The utility of this approach is yet to be determined. Prothrombin times (PT) and partial thromboplastin times (aPTT), as well as fibrinogen levels, are usually normal. Profound abnormalities of the PT and aPTT, however, are frequently reported. This is largely a laboratory artifact caused by the extreme erythrocytosis, which results in a relatively smaller volume of plasma being present in the whole blood sample. Coagulation assays are performed on blood anticoagulated with sodium citrate, and the citrate concentration in the anticoagulant is calibrated to chelate the plasma calcium and inhibit coagulation reactions. All coagulation assays include the addition of calcium chloride to neutralize the excess citrate and provide free calcium to mediate coagulation reactions. In patients with extreme erythrocytosis, the ratio of citrate in the collection tube to the volume of plasma is too high; therefore, excess citrate is present, and the standard amount of calcium chloride added during the performance of the PT and aPTT is insufficient to neutralize the excessive citrate, and the coagulation assays are frequently and factually prolonged. To avoid this problem, the clinician should calculate the relative amount of plasma compared with the normal amount and remove the corresponding volume of sodium citrate from the blood collection tube. Normal values can then be confidently anticipated in patients with erythrocytosis. A shortened fibrinogen half-life has been detected in some patients with PV and a significantly increased fractional catabolic rate of the plasma fibrinogen pool per day. In addition, elevated platelet β-thromboglobulin and plasma β-thromboglobulin levels are observed. The constellation of findings is indicative of increased platelet turnover. Prothrombin fragments F1 and 2, thrombin–antithrombin complex, and D-dimer levels are frequently elevated in PV patients. These are enzyme–inhibitor complexes or byproducts of active thrombosis that serve as a biochemical signature of the hypercoagulable state that characterizes PV.

Acquired von Willebrand syndrome occurs frequently in patients with PV and ET with over 1×10^6/L platelet numbers (see Chapter 133). This syndrome is characterized by a normal or prolonged bleeding time, normal factor VIII level, and normal von Willebrand factor (vWF) antigen level, but abnormal vWF ristocetin cofactor actively associated with a decrease or absence of large vWF multimers. This acquired defect resembles type II vWF disease. Because the molecular size of vWF is a major determinant of its adhesive function and the larger multimers are most active in achieving hemostasis, the deficiency of large vWF multimers is associated with a bleeding tendency. The decrease in the frequency of large vWF multimers occurs in patients with platelet counts over $1000 \times 10^9\,\text{L}^{-1}$. This abnormality has been reported not only with patients with severe thrombocytosis caused by MPN, but also in patients with reactive thrombocytosis. An inverse correlation between the proportion of large vWF multimers and platelet numbers has been observed. In addition, normalization of the platelet count is accompanied by restoration of a normal vWF multimer pattern. These findings suggest that thrombocytosis of any etiology may favor the adsorption of larger forms of vWF multimers onto platelet membranes, resulting in their removal from the circulation and subsequent degradation by platelet-associated proteases. Although patients with MPN frequently have bleeding tendencies, this is not the case in secondary thrombocytosis, possibly because of the limited periods of extreme thrombocytosis observed in such patients. Patients with PV with clinical courses punctuated by hemorrhagic events, extreme thrombocytosis, and acquired von Willebrand syndrome should avoid aspirin therapy if they are having a thrombotic episode but should be phlebotomized, and platelet-reduction therapy should be initiated. Patients with PV and acquired von Willebrand syndrome have recurrent bleeding from mucous membranes and the digestive tract, and easy bruising. These symptoms frequently resolve with normalization of the platelet count.

Deficiencies of one or more natural anticoagulants as well as the antiphospholipid antibody syndrome have been observed in patients with PV and thrombosis. These studies indicate that either familial or acquired antithrombin III deficiency, protein C or S deficiency, factor V Leiden mutation, or the prothrombin gene mutation may contribute to the hypercoagulable state observed in PV (see Chapter 138). Of note, although hyperhomocysteinemia caused by deficiency of cobalamin or folate can be found in 32% to 56% of PV patients, there is no agreement as to its role in the genesis of thrombotic episodes. Such inherited disorders associated with the erythrocytosis of PV provide a scenario that frequently favors thrombosis in affected individuals. In attempting to determine if a patient with PV and an active thrombosis has such an inherited predisposition, it is important to be aware that proteins C and S as well as antithrombin III levels can be low in patients with an ongoing acute thrombosis or liver cirrhosis. Normal prothrombin and factor VII levels in such patients eliminate liver cirrhosis as a cause of the reduction of these circulating anticoagulants. Individuals with inherited prothrombotic conditions frequently have levels of specific proteins below 10% to 20% of normal during periods of active thrombosis.

Whereas serum vitamin B_{12} concentrations have been found to be elevated in 40% of patients, serum vitamin B_{12}-binding proteins are elevated in 70% of patients. Hyperuricemia occurs in an overwhelming number of patients, and elevated histamine levels are also frequently observed. BM aspirates and biopsies obtained at the time of diagnosis of patients with PV are hypercellular and display characteristic erythroid, granulocytic, and megakaryocytic hyperplasia. The cellular elements (Fig. 70.10) are frequently morphologically normal. Iron stores are almost uniformly absent in pretreatment biopsy specimens. Significant increases in BM reticulin may be present in biopsies obtained early in the course but also may develop during the erythrocytotic phase and may be present for long periods before the onset of the post-PV MF. It is important to emphasize that individuals may have considerable BM fibrosis, which occurs as a consequence of the underlying MPN. The presence of minimal BM fibrosis should not be considered a harbinger of the development of post-PV MF. In patients with post-PV MF, a moderate-to-marked increase in reticulin fiber is observed, either simultaneously with or within 1 year of this clinical transformation.

Several investigators have attempted to use BM biopsy morphology as a differential diagnostic tool to differentiate between PV and secondary forms of erythrocytosis. The marked hypercellularity, erythroid and megakaryocytic hyperplasia with pleiomorphic enlarged megakaryocytes that are the hallmarks of MPNs are useful parameters for identifying such individuals (see Fig. 70.10). It is imperative to use the BM biopsy rather than the aspirate specimens for this purpose. It has been suggested that those PV patients with minor BM fibrosis are at an increased risk to develop a thrombotic episode or to evolve into post-PV MF but not acute leukemia during the course of their disease.

The pathologic appearance of the spleen in PV depends on the stage of the disease at which the organ is examined. Spleens from patients in the erythrocytotic phase of the disease are characterized by striking congestion with mature erythrocytes. Small numbers of hematopoietic precursor cells are frequently present. By contrast, spleens examined during the PV-related MF phase are characterized by prominent numbers of foci of extramedullary hematopoiesis, with representation of all BM precursor elements.

Allele-specific PCR methods or next generation sequencing can be used to detect the *JAK2V617F* or a *JAK2* exon 12 mutation in approximately 95% of patients with PV. The very high frequency of *JAK2V617F* in PV has dramatically improved our ability to diagnose this disease. Patients with isolated erythrocytosis associated with normal neutrophil and platelet counts but low serum EPO levels and the formation of erythroid colonies by peripheral blood mononuclear cells in the absence of EPO in vitro are the characteristic phenotype of patients with the exon 12 mutation. BM biopsies from these patients were slightly hypercellular with isolated erythroid hyperplasia. Megakaryocytes were morphologically normal and not clustered. The exon 12 mutations were frequently present at low levels in granulocyte DNA but were readily identifiable in endogenous erythroid colonies generated in vitro. Because granulocyte involvement with *JAK2* exon 12 mutations is low, it is important to sequence DNA from BM cells or from endogenous erythroid colonies generated in vitro to make this diagnosis (if available). At diagnosis, serum EPO levels in PV are either reduced or at the lower limits of normal. Even after normalization of the hematocrit, the serum EPO level in PV remains low in two-thirds of patients.

Arterial blood gas measurements are frequently performed to rule out hypoxia as a cause of erythrocytosis. In PV with extreme thrombocytosis, such routine measurements can prove to be misleading. Spurious hypoxemia can frequently be attributed to either significant leukocytosis or thrombocytosis caused by in vitro consumption of oxygen, the so-called *platelet and leukocyte larceny*. In this situation, pulse oximetry can be a useful tool for establishing the patient's true oxygenation status.

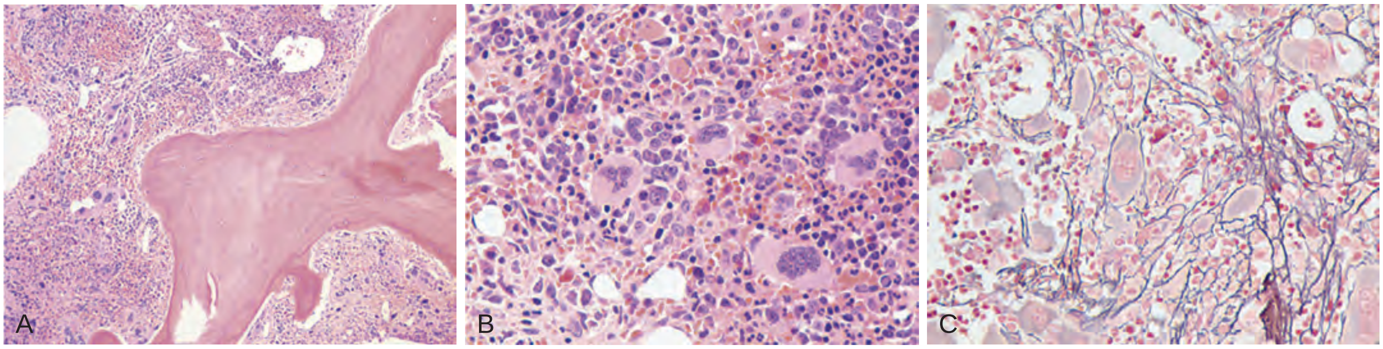

Figure 70.10 POST-POLYCYTHEMIC MYELOFIBROSIS. (A, B) Hyperplastic bone marrow with increases in all lineages, and megakaryocytic pleomorphism, with clustering. There are changes consistent with fibrosis, including streaming of hematopoietic cells and dilated sinusoids. (C) Reticulin fibers are increased, with prominent coarse fibers (grade MF2). (A, Hematoxylin-eosin [H&E] stain, ×100; B, H&E stain, ×400; C, reticulin stain, ×400.) *(From Kremyanskaya M, et al. Myeloproliferative neoplasms. In Salama M, et al. (eds). Atlas of Diagnostic Hematology. Elsevier, 2021.)*

CYTOGENOMIC ABNORMALITIES

The occurrence of nonrandom cytogenetic abnormalities in PV is anticipated because this is a feature of most hematologic malignancies. Such abnormalities have been observed without a single characteristic abnormality defined; the most frequent abnormalities are the gain of chromosome 9 as well as 9p, deletion of the long arm of chromosome 20, gain of the long arms of chromosome 1, trisomy 8 alone or co-occurrence of +8, +9, and deletion of chromosome 13 (Fig. 70.11). Balanced translocations are rarely but recurrently observed in PV although recently translocations involving JAK2, such as t(8;9)(p22;p24.1)/PCM1-JAK2), t(3;9)(q21;p24)/RPN1-JAK2, t(1;9)(p36;p24.1)/(PEX14-JAK2), t(9;22)(p24.1;q11.2)/BCR-JAK2 were described. At diagnosis, approximately 28% of patients have a recurrent clonal chromosome marker. Interphase fluorescence in situ hybridization (FISH) testing with 12 probes for loci most frequently associated with PV and other Ph^- MPNs occasionally identifies cryptic +9p, del(20q) or del(13q) abnormalities and thus may increase the frequency of detecting a chromosomal rearrangement at diagnosis to 29% to 30%.[42] However, interphase FISH (I-FISH) does not appear to significantly increase the detection rate in untreated patients. Among 452 patients with PV cytogenetically studied at the authors' institution between 1984 and April 2011, 28% had cytogenetic abnormalities at diagnosis. I-FISH studies alone (without cytogenetic examination) using an MPN panel of 12 probes revealed that 29% of patients had genomic changes (Fig. 70.12). The frequency of detection of cytogenetic abnormalities in PV increases over time, with 35% to 55% of patients having clonal cytogenetic abnormalities after extended follow-up and more than 80% of those patients in whom acute leukemia eventually develops. Progression from a normal to an abnormal karyotype is an important adverse prognostic parameter. Most of the PV-related chromosomal abnormalities are occurring in JAK2V617F mutated cells. However, clonal single cells studies have documented that abnormalities such as del(20q) and +8,+9 can occasionally precede acquisition of JAK2V671F mutation in single CD34 HPC, suggesting that clonality can occasionally precede development of JAK2V617F mutation.

Trisomy of the long arms of chromosome 1 is a recurrent abnormality present in about 4% to 6% of patients with PV with an abnormal karyotype. This abnormality has also been described in PMF and other myeloid malignancies. Specifically, 70% of patients with post-PV MF develop trisomy 1q as a result of unbalanced translocations. Trisomy 1q rarely occurs alone and is most frequently found translocated to another chromosome, creating an unbalanced +1q translocation. The recipient chromosome most frequently involved is chromosome 6 followed by chromosome 9. Jumping translocations are a rare recurrent cytogenetic phenomenon whereby a part of one chromosome is translocated to several recipient chromosomes, creating multiple related clones within a single patient. Jumping 1q in MPN occurs in 4.2% of cytogenetically abnormal MPN; 86% of such patients progress to AML after an average of 8 months, suggesting that 1q jumping translocations are associated with both disease progression and poor prognosis. Gain of 1q is most prevalent in patients with a history of PV and *JAK2V617F+* mutation (~50%) and is accompanied by an increased transcript level of *MDM4* (residing at 1q32.1). Since these patients have co-occurrence of either del(17p) or TP53 mutation, the current hypothesis is that gain of 1q leads to further dysregulation of the TP53 pathway and contributes to the progression of disease.[40]

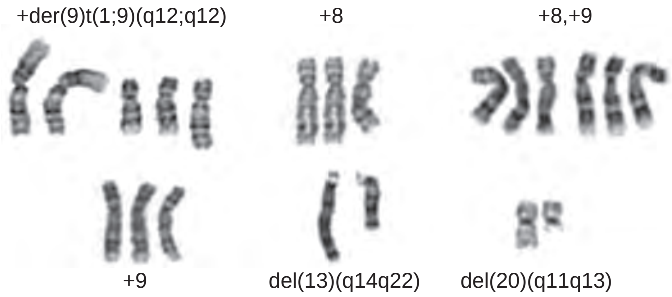

Figure 70.11 Most frequent chromosomal abnormalities associated with polycythemia vera at diagnosis include *(top row)* a gain of derivative(9)t(1;9), resulting in three copies of the long arms of chromosome 1 and three copies of the long arms of chromosome 9, including Janus kinase 2; gain of chromosome 8 and simultaneous gain of both chromosomes 8 and 9 *(bottom row)*; gain of chromosome 9 alone; interstitial deletion of chromosome 13; and interstitial deletion of chromosome 20.

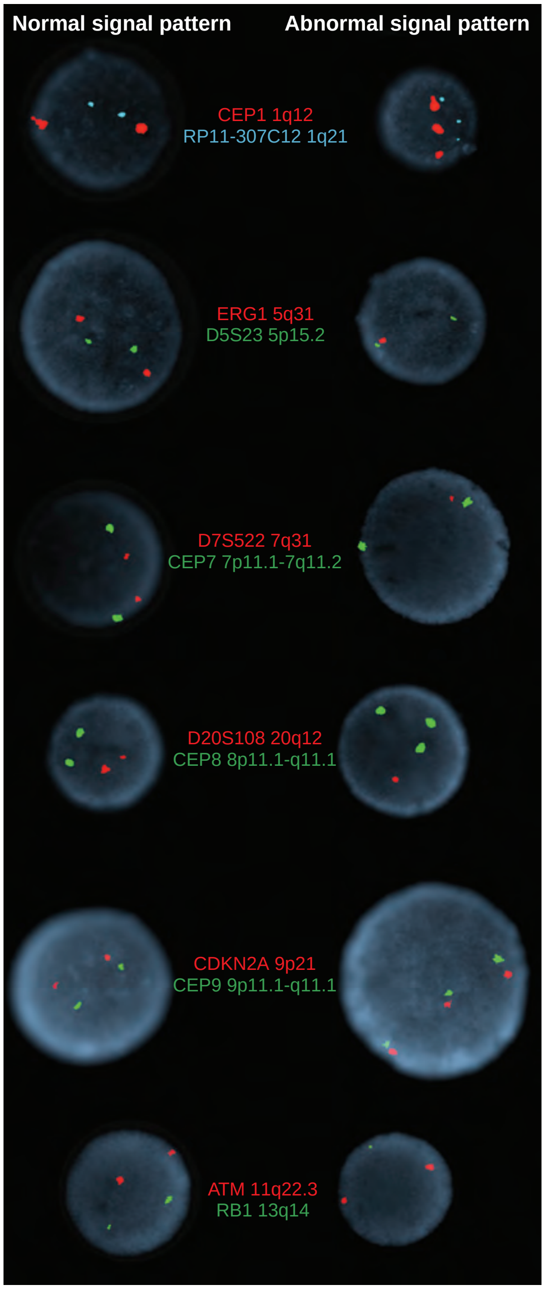

Figure 70.12 Myeloproliferative neoplasm fluorescence in situ hybridization (FISH) panel includes 12 loci on eight different chromosomes for detection of the most frequent chromosomal rearrangements when cytogenetics are either not available or in conjunction with conventional cytogenetics for detection of cryptic abnormalities. Discrepancies in frequency of abnormality detected by interphase FISH and conventional cytogenetics are present and often suggest a proliferative advantage of the abnormal clone.

Gain of chromosome 8 is a recurrent abnormality not only in Ph$^-$ MPN, but it is also one of the three most frequent abnormalities in MDS and is present in 10% of patients with malignant hematopoietic disorders of both myeloid and lymphoid lineages. The prognostic significance in PV is unknown. Some patients with PV with trisomy 8 do not acquire other abnormalities after 20 years. The simultaneous presence of both +8 and +9 is PV specific, and is observed in 3% to 4% of PV cases; it is rarely seen in other hematologic malignancies. In PV, trisomy 8 has been demonstrated in myeloid cells but not in lymphoid cells.

Trisomy 9 and gain of the short arms of chromosome 9 is most frequently and almost exclusively observed in PV. There are three types of 9p abnormalities in PV: (1) about 30% of patients have uniparental disomy of the 9p region; (2) numerical gain, such as different chromosomal rearrangements that contribute to trisomy, tetrasomy, or amplification of 9p; and (3) unbalanced translocations, of which the most frequent, +der(9)t(1;9) t(1;9)(q12, results in a trisomy of both 9p and 1q, and appears to be a relatively specific abnormality in PV patients (Fig. 70.13). This rearrangement provides an extra copy of mutated *JAK2*. Trisomy 9p and three copies of mutated *JAK2* are rare recurrent abnormalities resulting from unbalanced chromosome 9 translocations such as der(1)t(1;9)((q12;q13, der(1)t(1;9)p13;p13) der(18)t(9;18)(p13;p11)/der(9;18)(p10;q10) or isochromosome 9(p10). I-FISH has been used to detect cryptic chromosome 9 rearrangements. FISH has uncovered chromosome 9 rearrangements in 53% of patients with abnormal FISH patterns, indicating that a gain of 9p is the most frequent genomic alteration in PV. The association between the trisomy of 9p and PV was one of the keys to the identification of the *JAK2V617F* mutation. Cytogenetic studies of 9p and LOH indicate that the LOH is attributable to mitotic recombination that enables genetic variants to progress from a heterozygous to a homozygous state without change in DNA copy number.

Interstitial deletions of the long arms of chromosome 13 are not specific for PV and are more frequently observed in PMF than in PV. About 1% to 13% of cytogenetically abnormal patients with PV have del(13q). Among patients with del(13q), about 91% have breakpoints in 13q12–14 to q21–22 regions. Fine FISH mapping has defined the commonly deleted region (CDR) to 13q13.3-q14.3 encompassing Rb1 and two microsatellite loci, D13S319 and D13S25. Cryptic del(13q) occurs and is easily identified with the FISH method. Deletions are heterogeneous and may involve one, two, or all three loci, including Rb1. del(20)(q11q13), an interstitial deletion of the long arm of chromosome 20, is the second most common cytogenetic abnormality in PV (Fig. 70.14). Del(20)(q11q13) is not diagnostic of PV because it also occurs in PMF and ET, as well as in MDS, AML, and multiple myeloma. Heterogeneity of the breakpoints is suggested by the observation that two minimally deleted regions (MDRs) characterize different disorders. A 2.7-Mb region spanning D20S10-8 (proximal) and D20S481 (distal) is identified in Ph$^-$ MPN, and a 2.6-Mb region spanning R52161 (proximal) and Wi-12515 (distal) is found in other malignancies. Two CDR, CDR1 spanning 2.4 Mb between bands 20q11.23 and 20q12, and CDR2 encompassing 1.8 Mb within 20q13.12, have been identified. The commonly retained region (CRR)1 spans 1.9 Mb within 20q11.21 and CRR2 encompasses 2.5 Mb within 20q13.33. High-resolution genotyping has not revealed any somatic copy-neutral LOH within these regions. Investigations to date of candidate genes within the deleted segments have failed to identify any mutations within deleted segments. In contrast, haploinsufficiency of the *L3MBTL1* gene, the human homolog of the *Drosophila* L(3)MBT polycomb group tumor suppressor gene located on the 20q12 within a region commonly deleted in several myeloid malignancies, may play a role in erythropoiesis in PV. Downregulation of *L3MBTL1* expression in primary hematopoietic stem progenitor cells (HSPCs) causes enhanced commitment to and acceleration of erythroid differentiation. Moreover, overexpression of *L3MBTL1* in primary hematopoietic CD34$^+$ cells as well as in 20q cell lines limits erythroid differentiation. Therefore, haploinsufficiency of *L3MBTL1* may contribute to erythroid differentiation in PV. It has also been demonstrated that *L3MBTL1* is important for the normal progression of cells through mitosis because both overexpression and loss of activity can affect cell division. There is evidence that 20q deletions may impair the release of granulocytes into the peripheral blood. Some patients with PV and 20q deletion in BM cells have cytogenetically normal peripheral blood granulocytes, which has been attributed to del(20q) cells being preferentially retained or destroyed in the BM. The significance of this abnormality remains unknown because it may be dormant for many years before cells with del(20q) gain proliferative advantage. It is important to emphasize, however, that patients with del(20q) have been observed without further karyotypic instability for more than 10 years. Within ~3 Mb of minimal common deleted region spanning 20q12–20q12.12, a gene *STK4*, encoding Hippo kinase *MST1* is downregulated in patients with del(20q). Functionally deletion of these two genes in normal hematopoietic cells induces thrombocytopenia, enlarged platelets, and myeloid skewing. The level of *STK4* in patients with del(20q) is down regulated below haploinsufficiency. In JAK2V617F mouse model heterozygous Hippo kinase inactivation led to accelerated development of MF. This transformation was associated with cytokine production including IL1 and IL6, suggesting a novel pathway through chronic innate immune activation, and possible novel mechanism of disease progression in patients with del(20q).

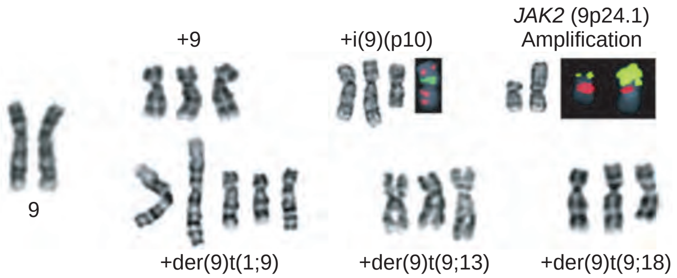

Figure 70.13 NUMEROUS CHROMOSOMAL ABNORMALITIES RESULTING IN TRISOMY, TETRASOMY, OR AMPLIFICATION OF THE SHORT ARMS OF CHROMOSOME 9. *JAK2*, Janus kinase 2.

Other rare recurrent chromosomal abnormalities may occur at the onset of the disease or are associated with disease progression. Both interstitial deletions of the long arms of chromosomes 5 and 7 have been reported at diagnosis and are associated with disease progression. Loss of P53 as a result of del(17p) or other chromosomal rearrangements is a rare finding in PV and appears to be related to disease progression. Del(17p) is not PV specific because it is found in many other myeloid malignancies.

Chromosome abnormalities including +8, +9, and del(20)(q11q13) are related to the biogenesis of the disease rather than occurring as a consequence of the chemotherapy. However, in some patients an abnormal clone (abnormalities of chromosome 5, 7, or 17) appears to develop as a consequence of exposure to chemotherapeutic agents. Some investigators have suggested that patients with cytogenetic abnormalities at diagnosis have a statistically significant poorer survival rate than those in whom a normal karyotype is observed. This influence of cytogenetic abnormalities on prognosis has, however, not been verified.

Among ~70% of PV patients who are cytogenetically normal, SNP array technology, a powerful complement to metaphase cytogenetics, revealed that at diagnosis 66% show copy number abnormalities and this number is extended to 100% of those who progressed to MF. Moreover, this exon-level technology when combined with an integrative approach such as mutational burden and cytogenetics revealed that even those PV or PV-related MF patients with a normal karyotype who are triple negative for MPN driver mutations harbor cells with cryptic recurrent lesions such as 9p21 cn-LOH or MDM4 strongly indicating that very few PV patients, when extensively worked up at diagnosis, are genomically normal.

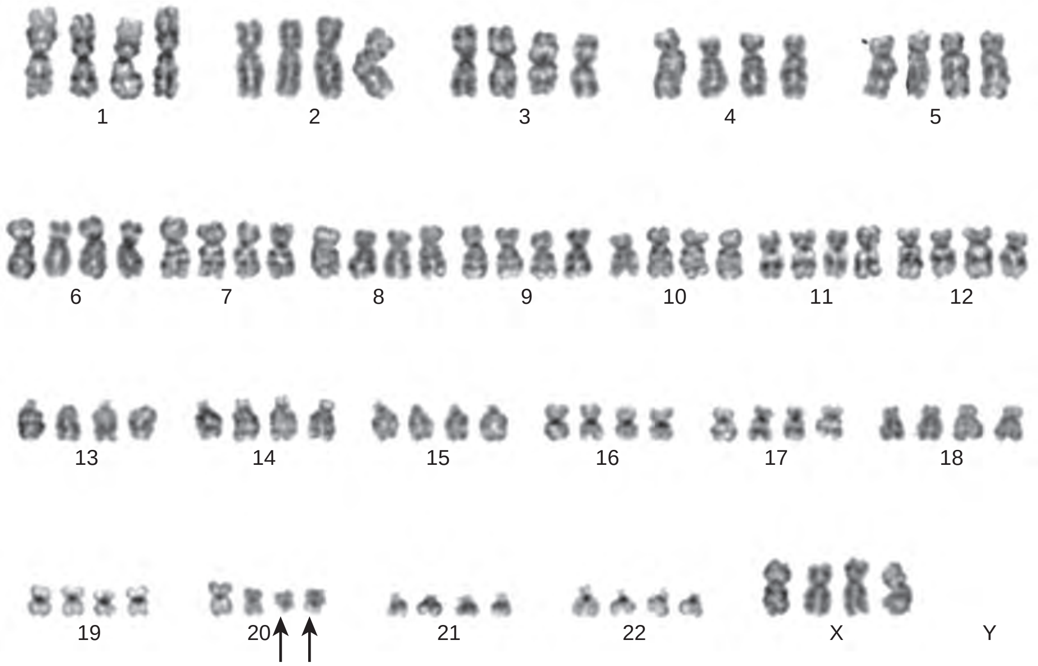

Figure 70.14 A karyotype from a dividing megakaryocyte showing *(arrows)* two copies of deleted 20q in a cell with 92 chromosomes.

DIFFERENTIAL DIAGNOSIS

In most patients, establishing the cause leading to erythrocytosis is not difficult. Initially, it is critical to be certain that one is dealing with a patient with absolute erythrocytosis. Testing for *JAK2V617F* and *JAK2* exon 12 mutations can be extremely useful in diagnosing PV and is now standard practice. The presence of splenomegaly is an important finding on clinical examination, and adjunctive laboratory findings include a normal arterial oxygen saturation, elevated LDH levels as well as biochemical evidence of iron deficiency in an erythrocytotic individual. Splenic sizing by ultrasonography can be useful in documenting splenic enlargement when the spleen is not palpable by physical examination.

It is initially important to differentiate PV from the large number of other causes of secondary erythrocytosis. Characteristically, the patient with PV will present with erythrocytosis, leukocytosis, thrombocytosis, and splenomegaly, and is positive for *JAK2V617F*. The BM biopsy shows hypercellularity with trilineage hyperplasia. In individuals who lack a mutated *JAK2*, it is important to determine the SaO_2 using an arterial blood gas, the carboxyhemoglobin level, and the $P_{50}O_2$ in patients with other family members with erythrocytosis to exclude obvious causes of secondary erythrocytosis. Because smokers' polycythemia is the most frequent cause of erythrocytosis, it is wise to measure carboxyhemoglobin levels early on in the investigation. In addition, a PaO_2 greater than 67 mm Hg or an O_2 saturation greater than 95%, as quantitated on an arterial blood gas, is helpful in ruling out hypoxic conditions that lead to erythrocytosis. In patients with intermittent hypoxia, such as sleep apnea syndrome or alveolar hypoventilation caused by obesity, such blood gas determinations can be normal. A low $P_{50}O_2$ is indicative of a hemoglobin mutant with high O_2 affinity, leading to tissue hypoxia and erythrocytosis. Patients with PV characteristically exhibit serum EPO levels below the 95% CIs for the range observed in normal control participants. It is not unusual to have a normal EPO level in some patients with hypoxic causes of secondary erythrocytosis, unless the hypoxia exists over an extended period of time. A normal EPO level cannot be used to exclude a hypoxic cause of erythrocytosis. EPO measurements do, however, remain an important diagnostic tool. Elevation of EPO levels in the face of erythrocytosis is indicative of a hypoxic cause of secondary erythrocytosis, but extremely low levels of EPO (<4 mIU/mL) are virtually diagnostic of PV.

Incorporating a mutational screen into the algorithm for investigating a case of suspected polycythemia helps to streamline the diagnosis of PV, although the presence of a *JAK2* mutation alone does not distinguish PV from PMF or ET. Clinical criteria for the diagnosis of PV have been defined by the WHO, which serves as a uniform platform with which to diagnose PV. These criteria are the consensus of many experts working in this field. It is important, however, for the clinician to realize that some patients undoubtedly have an MPN disorder resembling PV but do not fulfill all the diagnostic criteria of the PVSG or the WHO (Table 70.3). There will always be unusual cases with clinical characteristics that cannot be pigeonholed into a particular diagnostic category. If these patients have serious symptoms, the individual physician must make treatment decisions on the basis of the risk–benefit ratio for that patient.

A particularly difficult dilemma occurs when evaluating patients with isolated pure erythrocytosis. These patients have elevated RBC masses, normal WBC counts, normal platelet counts, no evidence of splenomegaly, and no evidence of any recognizable cause of secondary erythrocytosis. Clearly, some of these patients have *JAK2V617F*-positive PV or mutations of exon 12 *JAK2*, leading to isolated erythrocytosis. The PFCPs are caused by truncation of the EPOR, characterized by increased sensitivity of erythroid progenitor cells to EPO, and can be easily distinguished from PV. These patients frequently present in childhood, and this disorder is characterized by isolated erythrocytosis that is associated with an increased risk of thrombotic events. There is a strong family history of polycythemia. The BM progenitor cells are hypersensitive to EPO, yet no colonies form in the absence of EPO. The patient with profound erythrocytosis who is negative for *JAK2V617F* as well as exon 12 *JAK2* mutations and does not have erythrocytosis caused by smoking, cyanotic heart disease, an EPO-secreting tumor, sleep apnea, or resides at a high altitude remains a diagnostic dilemma. All patients should have a good family and drug history, an arterial oxygen saturation study and a carboxyhemoglobin measurement, and measurement or calculation of p50, and quantitation of 2,3BPG and serum EPO levels. If these studies are unrewarding, appropriate patients should then be investigated for mutations in the hypoxia-responsive element of the human *EPO* gene, HIF-2α and HIF-1α, VHL, PHD1,2,3, STAT5, and LNK. Some of these tests can be performed by commercial laboratories or by specialized academic reference laboratories (www.mayomedicallaboratories.com/articles/features/erythrocytosis/testing).

PV must also be differentiated from the other MPNs, such as CML, ET, and PMF. Such classification has major prognostic implications and influences important therapeutic decisions, including the use of tyrosine kinase inhibitors. With the distinctive cytogenetic abnormalities and molecular genetic abnormalities that are unique to CML (Philadelphia chromosome, *BCR-ABL* gene fusion), these two disorders should not be difficult to differentiate. Occasional patients with an MPN have been shown to have both *JAK2V617F* as well as *BCR-ABL*; whether this unusual occurrence that takes place in two different clones and thereby represents two independent MPNs or a single clone and is caused by the predisposition of such patients to acquire mutations in their hematopoietic cells is a subject of speculation.

Patients with PMF can present with abnormalities that are virtually indistinguishable from those of patients with PV-related MF. Almost 50% of PMF are *JAK2V617F* positive, but more than 90% of patients with post-PV MF are *JAK2V617F* positive. The survival of patients with the latter disorder is much shorter than that of patients with the former condition. Unusual patients with PMF may actually develop PV after iron supplementation or the institution of chemotherapy. ET with a borderline elevated hematocrit and PV with marked thrombocytosis can easily be confused. When the RBC mass is used as a definitive diagnostic test, a distinction between ET and the erythrocytotic phase of PV is usually readily apparent. This measurement is not widely available and can also be normal or actually low in patients with PV who are iron-deficient because of bleeding or excessive phlebotomy. *JAK2V617F*-positive ET patients were characterized by multiple features that resembled those of patients with PV, including higher hemoglobin levels, higher WBC counts, more prominent BM erythroid and granulocytic hyperplasia, a higher incidence of venous but not arterial thrombosis, low serum EPO levels, and lower serum ferritin levels. Surprisingly, *JAK2V617F*-negative patients who likely had calreticulin mutations had higher platelet counts. Furthermore, *JAK2V617F*-positive ET patients have a higher probability of developing PV with longer follow-up. Acquisition of homozygosity for the *JAK2V617* caused by homologous recombination is likely the critical event in the development of PV in *JAK2V617F* ET patients. Homozygosity for *JAK2V617F* occurs in at least 30% of patients with PV but is extremely rare in ET.

TABLE 70.3 World Health Organization Criteria for Polycythemia Vera

2016 WHO Diagnostic Criteria for PV
Major criteria:
1. Hemoglobin >16.5 g/dL in men, 16 g/dL in women, or hematocrit > 49% (men), >48% (women), or increased (RCM)[a]
2. BM biopsy showing hypercellularity for age with trilineage growth (panmyelosis) including prominent erythroid, granulocytic, and megakaryocytic proliferation with pleomorphic, mature megakaryocytes
3. Presence of *JAK2V617F* or *JAK2* exon 12 mutation
Minor criteria:
1. Serum EPO level less than the reference range for normal
Diagnosis requires meeting either all three major criteria or the first two major criteria and the minor criterion

[a] More than 25% above mean normal predicted value.

BM, Bone marrow; *EPO*, erythropoietin; *PV*, polycythemia vera; *RCM*, red cell mass; *WHO*, World Health Organization.

Data from Arber DA, Orazi A, Hasserjian R, et al. The 2016 revision to the World Health Organization classification of myeloid neoplasms and acute leukemia. *Blood*. 2016;127(20):2391–2405. *Blood*, 2016. 128(3):462–463.

PROGNOSIS

The prognosis of a patient with PV depends on the nature and severity of the complications that occur during the clinical course of that particular patient's disorder. In addition, an individual patient's prognosis depends on the duration of the erythrocytotic phase or the time to transition to post-PV MF or MPN-BP. Survival is also influenced by whether appropriate treatment is instituted during the erythrocytotic phase of the illness. Patients who have uncontrolled erythrocytosis are at an extremely high risk for the development of thromboses. Determination of the optimal management of patients with PV has been a difficult task because the disease, when treated, is associated with a survival period of approximately 17 years. Studies of new potential therapeutic interventions therefore require prospective studies with prolonged follow-up times before meaningful results can be generated determining their ability to improve upon overall survival.

Prognostic models in PV typically assess the risk of thrombotic events and the risk of leukemic transformation. Increasing age and history of vascular events have consistently proven to be independent predictors of developing additional thromboses in patients with PV. In the ECLAP trial, the incidence of cardiovascular complications was higher in patients older than 69 years of age, patients with a history of thrombosis, and patients with WBC counts higher than $15{,}000 \times 10^9\,L^{-1}$. Conventional cardiovascular risk factors, including hypertension, hyperlipidemia, diabetes, and smoking, are assumed to be associated with the same relative risk of developing thrombosis in PV patients as that observed in the general population. Although practicing hematologists are frequently concerned about elevated platelet counts in PV patients, several reports have failed to show any association between platelet count and thrombotic events, suggesting that therapies in PV targeting reduction of platelet numbers are ill conceived.

These data have led to stratification of therapy in patients with PV based on clearly identifiable risk factors (Table 70.4) of developing additional thrombotic events. The effect of *JAK2V617F* allele frequency on the prognosis of PV patients has been examined. More than 95% of patients with PV are *JAK2V617F* positive, and their mutational load can be determined by allele-specific or digital PCR. Approximately 30% of PV patients have a high *JAK2V617F* burden (>50%), and the remainder have a lower burden (<50%), with the small numbers being WT. Some investigators, but not all, have reported that high burdens of *JAK2V617F* in PV patients are associated with larger splenic volumes, more frequent aquagenic pruritus, a higher incidence of thrombotic events, and a higher rate of evolution into MF and MPN-BP.

High leukocyte counts ($>15{,}000 \times 10^9/L$) at the time of diagnosis have been identified in some studies as another independent predictor of developing a major thrombosis in PV patients. In addition, others have suggested that this parameter is predictive of evolution to MF and MPN-BP and an overall inferior survival time. In a retrospective study of 520 PV patients from 10 academic institutions across the United States, group-based trajectory modeling was used to identify

TABLE 70.4 Risk Stratification in Polycythemia Vera Based on Thrombotic Risk

Risk Category	Age >60 Years or History of Thrombosis	Cardiovascular Risk Factors[a]
Low	No	No
Intermediate	No	Yes
High	Yes	

[a] Hypertension, hypercholesterolemia, diabetes, and smoking (see text). Extreme thrombocytosis (platelet count $>1500 \times 10^9\,L^{-1}$) is a risk factor for bleeding. Its role as a risk factor for thrombosis is uncertain. An increasing leukocyte count has been identified as a novel risk factor for thrombosis, but confirmation is required.

Data from Finazzi G, Barbui T. How I treat patients with polycythemia vera. *Blood*. 2007;109:5104.

latent clusters of patients who follow distinct trajectories with regard to their hematologic laboratory data over time. The authors found that persistently elevated leukocyte trajectories were not associated with the hazard of thrombotic event, but were significantly associated with increased hazard of disease evolution. Interestingly, neither hematocrit nor platelet count was significantly associated with the hazard of thrombosis or disease evaluation.[32]

In a study of more than 1500 patients with PV, risk factors for survival included advanced age, leukocytosis, venous thrombosis, and abnormal karyotype. Median survival (14.1 years) was significantly worse than that of the age and sex-matched US population. A prognostic model based on the age, presence of leukocytosis, and venous thrombosis delineated risk groups with median survival of 10.9 to 27.8 years. In another study of 327 patients with PV from France and Sweden, multivariable analysis identified age greater than 70 years, leukocyte count greater than 13×10^9/L, and thrombosis at diagnosis as risk factors for survival. Patients with two or more of these risk factors had a 10-year relative survival of 26%, as opposed to patients with zero or one risk factors, who had a 10-year survival of 84% and 59%, respectively.

Recently, it has become more apparent that young patients with MPN comprise a unique disease population with different survival characteristics and potentially a more indolent disease course. A study at Mayo clinic identified 361 patients with MPN age 40 seen between 1967 and 2017, constituting 12% of all MPN patients seen during that time period. Compared to their older counterparts, younger patients with PV had lower incidence of arterial events and higher incidence of venous thrombotic events and a normal karyotype. Furthermore, PMF patients in this cohort had a lower incidence of high molecular risk myeloid malignancy gene mutations. With a median follow-up of 11.3 years, leukemic transformation was documented in 4% of PV patients. Median survival in young patients was 37 years compared to 22 years for patients 41 to 60 years and 10 years for patients over 60 years.[43] In order to take a look at the youngest MPN population, a recent systemic review evaluated patients with MPN diagnosed before 20 years of age.[44] They identified 75 cases of PV. The median age at diagnosis was 12 years for PV patients. Half of the patients were asymptomatic at diagnosis. Interestingly, 73% of these patients were triple negative for driver mutations suggesting that these individuals might actually have an inherited form of erythrocytosis. The incidence of thrombosis was 9.3% during the follow-up period. Venous events predominated. The risk of disease evolution was low with 2% developing MF and no reports of MPN-BP, however the median follow-up was only 50 months. While this data is not mature enough to make any realistic conclusions, it does point out that the prognosis for younger patients should not be based on risk factors used for an older population.

The choice of therapeutic agents used to treat the erythrocytotic phase of PV clearly influences patient outcomes. The use of alkylating agents is associated with an established risk for leukemic transformation or evolution to MDS. Clearly, this risk is also associated with increased duration of the disease. The effect of HU on leukemic transformation rates is limited, if any. In addition, the influence of long-term IFN therapy on disease outcomes is not at present clearly defined.

As the mutational landscape in myeloid malignancies takes a prominent role and various prognostic scoring systems based on mutational analysis become more standardized for patients with MF, attempts are being made to use mutational analysis to help prognosticate PV and ET patients as well. A study of 906 molecularly-annotated patients at Mayo Clinic and University of Florence, including 502 ET and 404 PV patients, tried to integrate genetic information together with clinical information for predicting survival. Multivariable analysis identified spliceosome mutations, and specifically in PV, SRSF2 to adversely affect MF free and overall survival. They were able to confirm the independent survival effect of adverse mutations, age greater than 67 years, leukocytosis $\geq 15 \times 10^9$/L and thrombosis history in PV patients and thus develop and validate mutation-enhanced international prognostic systems (MIPSS) which they reported was superior to the conventional scoring systems.[45]

THERAPY

The cumulative duration of survival for PV patients treated with modern strategies is between 15 and 17 years. Despite the implementation of standard therapeutic strategies, the mortality rate of PV patients is increased by 1.84 compared with age- and sex-matched populations. The primary goals of treatment are to reduce the risk for thrombosis and ameliorate the PV symptom burden. At present, therapeutic strategies which prevent evolution to MF and/or MPN-BP are not available. The European Leukemia Net (ELN) expert panel defined a complete response as a hematocrit less than 45% without phlebotomy, platelet count less than 400×10^9/L, leukocyte count less than 10×10^9/L, normal spleen size, and no disease-related symptoms.[46] However, in a study of 261 patients with PV who were given HU and followed up for a median of 4.4 years, no association was observed between achieving an ELN or a hematocrit response and better survival or fewer vascular complications. No particular platelet or leukocyte count could be shown to be protective against thrombosis. The ELN response criteria were updated in 2013, but have not been validated to predict survival or progression to MF or AM. Therapy is also stratified based on the presumed risk of an individual patient to develop additional thrombotic episodes, with low-risk patients being treated with phlebotomy therapy alone plus a therapy directed toward paralysis of platelet function, and high-risk patients receiving not only phlebotomy plus antiplatelet therapy but also some form of myelosuppressive therapy (HU, IFN, busulfan, melphalan, ruxolitinib). At present, the therapeutic goals are to reduce the risk of thrombosis by normalizing the hematocrit levels to 45% (some experts advocate reducing the hematocrit to 42% in females) based on a randomized prospective study that demonstrated a decreased risk of cardiovascular morbidity and mortality with a goal hematocrit of less than 45% compared to 45% to 50%.[30] Previous studies have indicated a lack of a relationship between thrombocytosis at diagnosis or during the period of follow-up with thrombotic complications. Whether therapy should be directed at normalization of platelets remains uncertain at present and should not be pursued unless within the context of a clinical trial. Extreme thrombocytosis ($>1 \times 10^9$/L), if associated with spontaneous hemorrhage, is an indication for normalization of platelet numbers. Phlebotomy therapy alone is the standard of care for low-risk PV patients (see box on General Principles of Therapy).

A series of studies, although completed more than 30 years ago, by the PVSG answered several very important questions regarding the efficacy and associated complications of particular therapeutic modalities. These investigations have aided in the identification of optimal therapy for individual patients, which must be selected on the basis of age and comorbid disease status to minimize treatment-related complications.

The first PVSG randomized trial (01 trial) evaluated three treatment strategies: (1) phlebotomy alone to maintain the hematocrit level at less than 45%; (2) intravenous ^{32}P at 2.3 mCi/m^2 repeated every 12 weeks, if needed (maximum, 5 mCi per dose), supplemented by phlebotomy to maintain the hematocrit level at less than 45%; and (3) myelosuppression with chlorambucil 10 mg/day orally for 6 weeks and then daily on alternate months with necessary dose reductions and supplemental phlebotomy. More than 400 patients were randomly assigned to this protocol. The median survival duration from entry into the study until death was 9.1 years for patients treated with chlorambucil, 10.9 years for those treated with ^{32}P, and 12.6 years for the phlebotomy group. Long-term survival was inferior for patients treated with chlorambucil compared with those treated with ^{32}P or phlebotomy. An early finding was the appearance during the first 5 years of a significant excess of deaths from MPN-BPin the chlorambucil arm, which reached 17% after 15 years of follow-up. As a result, the chlorambucil arm was discontinued, and patients were assigned randomly to one of the other two arms. Even though no statistical difference in overall survival between ^{32}P and phlebotomy alone was apparent through the first 10 years, the morbidity and mortality associated with each type of therapy were attributable to distinctly different causes. Thrombosis as a cause of death was much more frequent in the phlebotomy-only group during the first 5 to 7 years

GENERAL PRINCIPLES OF THERAPY

1. The etiology of erythrocytosis must be correctly categorized to be certain the patient has polycythemia vera (PV). This will avoid inappropriate exposure of patients with nonmalignant disorders to the adverse effects of myelosuppressive agents. To this end, a major contribution is played by incorporating molecular marker testing (*JAK2V617F* and exon 12 *JAK2* mutational determinations) in the diagnostic workup, and in this way, early phases of PV can be recognized as well. In individuals with erythrocytosis without a *JAK2* mutation, search for causes or secondary causes of erythrocytosis as well as inherited disorders that lead to erythrocytosis, which includes mutations in *EPOR*, *VHL*, *PHD2*, *HIF-1*, and *HIF-2*.
2. Therapy should be individualized.
3. Initially, the hematocrit should be reduced to 45% as soon as possible. The speed of phlebotomy will depend on patients' general medical conditions (250–500 mL every other day). Elderly patients with compromised cardiovascular or pulmonary systems should be more carefully phlebotomized (twice a week), or smaller volumes of blood should be removed.
4. Hematocrit levels should be consistently maintained at 45%.
5. The use of chemotherapeutic agents should be avoided in low-risk PV patients, and treatment with hydroxyurea, interferon (IFN), or ruxolitinib should be reserved for high-risk patients or patients with severe uncontrolled systemic symptoms. Be on the lookout for toxicities from each of these agents.
6. Hyperuricemia is treated with allopurinol (100–300 mg/day).
7. Pruritus may be improved with PV-directed therapy (phlebotomy, hydroxyurea, or IFN). Empiric therapy with antihistamines can be useful in selected patients. Selective serotonin uptake inhibitors (paroxetine 20 mg/day or fluoxetine 10 mg/day) or phototherapy can also be of use. Dramatic relief, however, can be achieved in almost all cases with the institution of ruxolitinib.
8. Elective surgery or dental procedures should be delayed until hematocrit levels have been normalized for more than 2 months. Aspirin should be held before surgery. If emergency surgery is contemplated, phlebotomy and cytapheresis should be pursued.
9. Women and men who are contemplating having children should be treated by phlebotomy plus low-dose aspirin therapy (81 mg/day) or with IFN-α to avoid teratogenic effects of chemotherapy. Such avoidance will also prevent deleterious effects on fertility. During pregnancy, therapy is frequently not necessary; if it is, phlebotomy plus low-dose aspirin should be exclusively used. If phlebotomy control is inadequate, treatment with IFN-α should be pursued.

of follow-up. Analyses of factors associated with thrombosis revealed that the performance of phlebotomy, the rate of phlebotomy, advancing age, and history of previous thrombosis were statistically significant factors predictive of this outcome. Historical studies have raised concerns about therapy with phlebotomy alone. The need for more than four therapeutic phlebotomies a year in the phlebotomy-alone arm was associated with an increased thrombotic risk. This led to the belief that frequent phlebotomy requirements were detrimental and necessitated cytoreductive therapy. However, overall survival and risk of evolution to MF and MPN-BP were lower in the phlebotomy alone arm. Iron deficiency is often present at diagnosis in PV patients and is also a consequence of repeated therapeutic phlebotomy; but in fact, it should be viewed as a therapeutic goal to further limit erythropoiesis. Iron deficiency however, can be associated with a number of clinical signs and symptoms, including fatigue, glossitis, restless leg syndrome, pruritis, dysphagia, cheilosis, koilonychia, fatigue, global weakness, cognitive deficits, neuromuscular disturbances, and pica syndrome. The neurocognitive effects of iron deficiency have been termed "foggy brain syndrome" and can limit PV patients in their successful performance of complex activities. Fatigue as a general symptom of non-anemic iron deficiency is likely related to the ubiquitous requirement for iron in all cells, particularly for the formation of heme as part of myoglobin, cytochromes, and nitric oxide synthase as well as in multiple enzymes required for the generation of adenosine triphosphate. Myoglobin is the oxygen storage protein in not only erythroid cells but also skeletal and cardiac muscle. In fact, iron repletion in non-anemic iron-deficient patients with congestive heart failure resulted in improved function, exercise tolerance, quality of life, and a significant reduction in recurrent hospitalizations, cardiovascular mortality, and all-cause mortality. Furthermore, iron is critical for energy metabolism due to its contribution to heme-containing enzymes such as cytochrome *c* (in the electron transport chain) and cytochrome *c* oxidase (in the oxidative phosphorylation pathway) as well as (2) non-heme-containing enzymes including NADH dehydrogenase and succinate dehydrogenase (in the respiratory chain) and aconitase (in the Krebs cycle). Lastly, iron is a necessary component of key proteins involved in DNA replication, repair, and cell cycle progression. Hepcidin, the master regulator of iron metabolism, is regulated by circulating iron levels, erythroblast secretion of erythroferrone, and inflammation. Insufficiently suppressed hepcidin given the degree of iron deficiency in PV patients strongly suggests that disordered iron metabolism is an important component of the pathobiology of PV. These findings have led to therapeutic trials aiming to restore iron stores but consistently normalize hematocrit levels with the administration of a hepcidin mimetic. The outcome of this phase II trial is eagerly awaited.[47]

In contrast, the use of ^{32}P led to a lower rate of thrombosis during the first 5 years of the PVSG study, but the incidences of leukemias, lymphomas, and nonhematologic malignancies increased during the next 5 years to nearly 10%. After a 15-year period of observation, the incidences of leukemia and lymphoma in the chlorambucil group had risen to 17%. A statistically significant increase in skin and gastrointestinal cancers occurred in the ^{32}P- and chlorambucil-treated cohorts compared with the group treated with phlebotomy alone (see box on Algorithm for Management of Patients With Polycythemia Vera). Based on these studies, therapy with chlorambucil and ^{32}P are no longer recommended.

Impetus for the use of nonchemotherapeutic agents for the treatment of PV was provided by an extensive natural history study of 1213 patients reported by the Gruppo Italiano Studio Policitemia. They showed that the age- and gender-standardized mortality rate of patients with PV was 1.7-times greater than the mortality rate of control participants in the general Italian population. In addition, four times as many patients who had previously received ^{32}P, alkylating agents, or HU died of cancer compared with patients treated with phlebotomy alone. When this group combined the total number of deaths and the number of nonfatal myocardial infarctions and strokes, they found an unsatisfactory risk-to-benefit profile in patients treated with chemotherapeutic agents and suggested that antithrombotic strategies, such as low-dose aspirin, be carefully evaluated for use in the care of patients with PV.

PV platelets are known to have a generalized abnormality of arachidonate metabolism that is characterized by enhanced synthesis of thromboxane A_2, which likely reflects stimuli to platelet activation. The exact mechanism responsible for enhanced platelet synthesis of thromboxane A_2 in PV remains unknown and requires further investigation. A low-dose aspirin regimen (50 mg/day for 7 to 14 days) has been shown to suppress more than 80% of the excretion of the metabolites of thromboxane A_2. A pilot study was performed in which the toxicity of low-dose aspirin therapy in PV patients was evaluated. A very low-dose aspirin regimen (40 mg/day) was chosen to prevent thrombosis yet minimize the risk of bleeding. After follow-up of the low-dose aspirin treatment group and control group, low-dose therapy was shown not to be associated with an increased incidence of bleeding complications. Aspirin therapy was well tolerated and was associated with complete inhibition of platelet cyclooxygenase activity. A large, randomized, placebo-controlled clinical trial testing the risk-to-benefit ratio of low-dose aspirin therapy in preventing thrombotic episodes in PV has been completed.[29] Treatment with low-dose aspirin (100 mg/day) compared with placebo reduced the risk of the combined end points of nonfatal myocardial infarction, nonfatal stroke, pulmonary embolism, major venous thrombosis, or death from cardiovascular courses. Overall mortality and cardiovascular mortality, however, was not reduced significantly by aspirin therapy. Importantly, the incidence of major bleeding episodes was not significantly increased in the aspirin group. It is important to emphasize that patients require aggressive phlebotomy therapy to

ALGORITHM FOR MANAGEMENT OF PATIENTS WITH POLYCYTHEMIA VERA

Low-risk young patients (age <60 years) and no history of thrombosis, platelet count $<1.5 \times 10^6\,\text{mm}^{-3}$

Phlebotomy + low-dose aspirin (81 mg/day) to maintain hematocrit lower than 45%. Aspirin should be used with caution in patients with histories of a hemorrhagic episode or with extreme thrombocytosis ($>1.5 \times 10^6\,\text{mm}^{-3}$) or acquired von Willebrand syndrome.

↓

Thrombosis or hemorrhage
Systemic symptoms
Severe pruritus refractory to histamine antagonists
Painful splenomegaly

↓

Hydroxyurea 15–20 mg/kg or

↓

Pegylated IFN 45–180 μg/week (alter dose depending on response and toxicity) or ruxolitinib 10 mg twice daily and titrate dose depending on the response. →

In a patient with a prior thrombosis or a history of bleeding due to acquired von Willebrand's syndrome, normalization of platelet numbers is necessary. If platelet control is inadequate or the patient cannot tolerate interferon, one option is the use of anagrelide. In this case, supplemental phlebotomy is required to maintain hematocrit lower than 45%, and the use of hydroxyurea should be considered, especially if the patient continues to have thrombotic episodes.

↓

If the patient has increasing splenomegaly, systemic symptoms, or repeated thromboses despite adequate dose of hydroxyurea (2 g/day) or if unable to tolerate hydroxyurea, start ruxolitinib 10 mg twice daily and titrate up or down based on hematologic parameters. Ruxolitinib therapy should be especially considered in patients with severe aquagenic pruritis which is unresponsive to other myelosuppressive therapies. If patient is infected with COVID-19 virus do not discontinue ruxolitinib.

For patients >80 years of age who cannot tolerate the other therapeutic approaches outlined above or have access issues to medical care, low doses of busulphan should be administered until the blood counts are normalized. Therapy should then be discontinued since patients frequently enjoy drug-free prolonged remissions lasting months. Therapy should only be reinstituted at the time the blood counts begin to be elevated again. Such therapy with alkylating agents should not be used in younger patients. It should be mentioned that the sequential use of hydroxyurea and alkylating agents is associated with an increased risk of leukemia and should be avoided. As a general approach we suggest periodic supplemental phlebotomy to achieve hematocrit control rather than administering increasing doses of myelosuppressive agents and risking drug-related adverse events.

Painful splenomegaly

↓

Patients should be treated with ruxolitinib.
If unable to tolerate or insufficient response
Splenectomy + continued systemic therapy.

↓

High-risk patients (age >60 years), previous thrombosis, platelet count $>1.5 \times 10^6\,\text{mm}^{-3}$

Phlebotomy to hematocrit of 45%

Aspirin (81 mg/day) to be given only in patients with platelet counts $<1.5 \times 10^6\,\text{mm}^{-2}$

Myelosuppressive therapy with hydroxyurea 30 mg/kg orally for 1 week then 15–20 mg/kg

or 45–180 μg/week of pegylated IFN.

↓

If patient continues to have thrombotic episodes and has extreme thrombocytosis or cannot tolerate hydroxyurea or pegylated IFN, initiate therapy with ruxolitinib 10 mg twice daily and titrate the dose to achieve hematocrit control. If the patient is refractory to other agents and is >80 years of age add intermittent busulphan.

If on busulphan, stop when blood counts are normalized or platelet count is lower than $300{,}000\,\text{mm}^{-3}$.

Occasional supplemental phlebotomy if hematocrit is >45%; when these elderly patients relapse (patient is symptomatic) initiate busulphan therapy again at same dose.

Patient age >70 years
Phlebotomy + low-dose aspirin + hydroxyurea

↓

No response or poor compliance
Ruxolitinib or busulfan.

the appropriate target hematocrit levels as well as the appropriate use of myelosuppressive agents as primary therapy, with the addition of aspirin serving as an adjunct to this strategy. The conclusions of this study have been questioned by several investigators. In addition, a retrospective analysis performed by independent investigators of the 1630 patients treated by the ECLAP group has concluded that low-dose aspirin therapy in PV patients was associated with a statistically nonsignificant reduction in the risk of fatal thrombotic episodes without an increased risk of bleeding. This meta-analysis is surely not a ringing endorsement of the widespread use of aspirin therapy, which is a strategy that has been indiscriminately used worldwide to treat such patients. Because it is unlikely that the value of aspirin therapy will be examined in a properly powered randomized trial, it is suggested that since aspirin therapy is a relatively innocuous therapy it should be used in high-risk patients judiciously. However, it should be avoided in patients with extremely high platelet counts who are at risk for hemorrhage.

After the disappointing results experienced with the alkylating agent chlorambucil, the PVSG began a nonrandomized phase II investigation of HU, an S-phase–specific ribonucleotide reductase inhibitor. The hope was that this agent would be nonleukemogenic. Of 53 patients with PV treated with HU who had never received other forms of myelosuppression, after follow-up for a median period of 8.6 years and a maximum follow-up of 795 weeks, 5.4% developed MPN-BP compared with 1.5% of patients treated with phlebotomy alone on the original PVSG randomized study.

In a comparable trial from Israel, 71 patients were treated with HU for a mean duration of 7.3 years. Remarkably, the incidence of thrombosis was only 6%, indicating the potential of HU to lower the incidence of thrombosis in patients with PV, confirming an observation previously made by another group. The incidence of MPN-BP in the Israeli trial was 5.6%. In another retrospective series, the incidence of MPN-BP and myelodysplasia in patients with PV treated with HU alone was 6.9%. In patients treated first with busulphan and then HU, the rate of MPN-BP and myelodysplasia was 13.8%. A recent propensity score analysis of patients enrolled in the ECLAP study examined 1042 patients who during follow-up received only phlebotomy or HU with a goal of hematocrit less than 45%. Over comparable period of follow-up they demonstrated superiority of HU over phlebotomy alone with respect to the incidence of fatal/not-fatal cardiovascular events. In addition, this same population of patients was used to demonstrate a significant advantage of HU over phlebotomy alone with respect to the proportion of non-fatal arterial thrombosis. This advantage was not present at reducing unprovoked venous thromboembolic events. Twenty-two patients developed MPN-BP and MDS in the ECLAP study that enrolled 1638 patients. AML and MDS were diagnosed after a median of 8.4 years from the diagnosis of PV; the variable associated with progression was older age, but overall disease duration (>10 years) failed to reach statistical significance. Exposure to ^{32}P, busulphan, and pipobroman but not HU alone had an independent role in producing an excess risk for progression to MPN-BP and MDS compared with treatment with phlebotomy or IFN.

The leukemia-promoting potential of HU has been readdressed in two additional studies. Kiladjian and coworkers reported the results of a randomized trial of HU versus pipobroman that was initiated in 1980; the overall survival was 20.3 years in the HU-treated group compared with 15.4 years for the patients treated with pipobroman. The incidence of MPN-BP and MDS in the pipobroman group was dramatically higher, which is not unexpected because pipobroman is an alkylating agent. This trial was designed with a cross-over option, but 93 patients only received pipobroman. The incidence of MPN-BP and MDS in the patient group that only received HU was 7.3%, 10.7%, and 16.6% at 10, 15, and 20 years, respectively. Since a control arm treated with phlebotomy alone was not included, one cannot determine if this rate of evolution to MPN-BP/MDS represents the natural history of PV or a possible limited leukemogenic effect of HU. Interestingly, no difference in the incidence of vascular events was seen between the two arms. This same question was again addressed in a nested case–control study performed in Sweden. The most important observation was that 25% of patients with various

MPNs (68% had PV) who evolved to MPN-BP and MDS had not been exposed to any chemotherapeutic agent, indicating that the risk of leukemic evolution was higher than had been previously appreciated. The use of radioactive phosphorous and alkylating agents, but not HU, was associated with a higher rate of MPN-BP and MDS. These reports indicate that nontreatment-related factors play a major role in the development of AML and MDS, and the contribution of HU based on the best available evidence is at best minimal. These data and the ease of administration make HU a very useful chemotherapeutic agent in older, high-risk patients with disease that cannot be controlled with phlebotomy alone. Excessive myelosuppression, macrocytosis, hypersegmentation of polymorphonuclear leukocytes, cutaneous actinic keratosis, squamous cell carcinoma of the skin, hyperpigmentation of the skin and nail beds, stomatitis, painful leg ulcers, creatinine elevations, and jaundice have been attributed to the use of HU. Aphthous and leg ulcers occur in 9% of patients, usually after approximately 10 months of therapy (Fig. 70.15). Rarely, cycling of platelet and leukocyte counts but not RBCs occurs while patients are being treated with HU. In this situation, the authors have maintained patients on a fixed dose of HU rather than chasing cycling platelet counts. In addition, the use of HU requires patient compliance and careful monitoring of blood counts to avoid the sequelae of excessive myelosuppression.

Patients resistant to HU are defined by need for additional phlebotomies, increasing splenomegaly, increasing leukocytosis in the face of the highest tolerable dose. HU resistance develops in 20% to 30% of PV patients after a median time of 4.6 months and is associated with an increased risk of developing a thrombosis, disease progression and a limited survival. The patients have an unfavorable mutational profile involving JAK2V617F homozygosity rather than heterozygosity as well as mutations in genes encoding chromatin modifiers, spliceosome genes, or TP53.[48] Anagrelide, a selective inhibitor of platelet production, is occasionally used to treat uncontrolled thrombocytosis not responsive to HU, interferon, or ruxolitinib in PV patients with thrombotic or hemorrhagic complications. This agent is nonleukemogenic and acts by impairing megakaryocyte maturation. Its use leads to a selective reduction in platelet numbers, and it has been effective in patients refractory to HU and IFN. This drug does not effectively control the erythrocytosis and leukocytosis or systemic symptoms associated with PV, and therefore has limited utility and is best used as a supplement to phlebotomy therapy. The time to complete response generally ranges between 17 and 25 days. The dose of anagrelide required to control thrombocytosis remains constant over time in most patients. When anagrelide is discontinued, platelet counts returned to pretreatment levels within 5 to 7 days. The simultaneous administration of anagrelide and low-dose aspirin has been reported to lead to a significant increase in bleeding manifestations. Clinicians presume that the effects of anagrelide observed in ET patients will be relevant to patients with PV. This assumption has not been tested in a randomized clinical trial. Anagrelide therapy should be reserved for patients with recent thromboses (e.g., stroke, migraines, erythromelalgia) and with thrombocytosis that cannot be controlled with IFN, HU, or ruxolitinib therapy alone. It can also be used in combination with HU to minimize adverse events that accompany the use of each drug alone. Anagrelide should not be used in pregnant patients because it can easily cross the placenta, leading to adverse effects on the platelet count of the fetus.

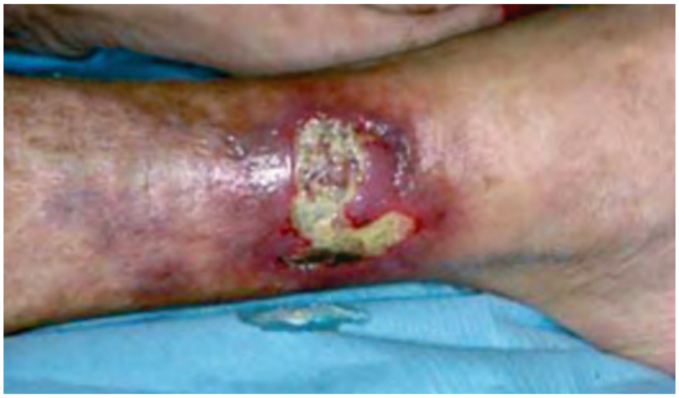

Figure 70.15 EXAMPLE OF A HYDROXYUREA-INDUCED LEG ULCER. *(From Soutou B, Aractingi S. Myeloproliferative disorder therapy: assessment and management of adverse events–a dermatologist's perspective. Hematol Oncol. 2009;27:11.)*

Approximately 15% to 20% of patients treated with anagrelide discontinue the medication because of nonmyelosuppressive side effects. The spectrum of adverse effects involved neurologic (headaches and dizziness), cardiac (vasodilatation, fluid retention, congestive heart failure, palpitations, and tachycardia), and gastrointestinal (nausea) toxicities. These toxicities reflect the novel mechanism of action of anagrelide as a cyclic nucleotide phosphodiesterase inhibitor. Anagrelide should be used with caution in patients with known or suspected cardiac disease because of its ability to promote fluid retention. Because many patients with PV are elderly, careful attention to fluid status should be maintained to avoid slipping into congestive heart failure after the initiation of anagrelide.

IFN-α therapy has been explored for several decades for the treatment of PV patients, but its beneficial effects have been more greatly appreciated during the past 12 to 17 years. Its effects on myeloid malignancies are likely the consequence of its broad range of biologic activities, including direct effects on malignant cells, enhancement of antitumor immune responses, induction of proapoptotic genes, inhibition of angiogenesis, and promotion of the cycling of dormant malignant stem cells. The induction of apoptosis by IFN-α involves the activation of a number of IFN-stimulated genes including TP53 that mediate this response. Gene expression studies have identified more than 15 IFN-stimulated genes with proapoptotic functions. Although these IFN-stimulated genes alone are probably not sufficient to induce apoptosis, their cumulative effects likely result in apoptosis. Type 1 IFNs suppress the ability of normal human HPCs to proliferate in vitro in the presence of cytokine combinations. IFN-α acts directly against HPCs; this inhibitory activity has been documented using CD34$^+$ cell populations. PV CD34$^+$ cells are more sensitive to the inhibitory effects of IFN-α than normal HPCs.

The ability of type 1 IFNs to inhibit HPC proliferation and maturation has been documented to occur independently of the STAT pathway. Type 1 IFNs activate the p38 MAP kinase, a proline-directed serine/threonine kinase that is required for IFN-stimulated gene transcription through IFN-sensitive response elements (IRSE). The pharmacologic blockade of p38 in IFN-treated PV HPCs reverses the inhibitory effects of IFN-α. Activation of p38 MAP kinase results in mitochondrial translocation of the proapoptotic protein Bax, leading to the induction of apoptosis.

IFN has also been shown to be able to affect HSC behavior. High levels of IFN-α induce murine HSCs to exit from a normally quiescent state and to transiently proliferate. Several studies using either primary PV CD34$^+$ cells or murine models of *JAK2V617*-positive PV have provided evidence that IFN-α is able to selectively deplete malignant PV stem cells. IFN has also been shown in murine models to promote the predominance of JAK2V617F positive megakaryocyte-biased stem cells with decreased long-term repopulating potential. Such a skewing of stem cell potential could lead to a reduction in JAK2V617F VAFs.[49]

Whole-blood transcriptional profiling studies demonstrated downregulation of HLA genes in MPNs and it has been postulated that this could be one of the ways that MPN cells evade immune surveillance with deregulation of several immune genes and contributing to the risk of second cancers which has been demonstrated in MPN patients. Treatment with IFN-alpha2 results in upregulation of these downregulated HLA genes.

In the United States, the pioneering independent studies by Richard Silver and Harriet Gilbert first documented the clinical effectiveness of IFN-α in controlling erythrocytosis as well as pruritus and other constitutional symptoms in PV patients, and Austrian and French groups reported during the same period evidence that IFN-α was also effective in reducing thrombocytosis in ET patients. A number of clinical trials have been performed subsequently using several different commercial preparations of IFN. In almost all PV and ET trials, IFN-α therapy rapidly normalized platelet numbers and corrected the degree of leukocytosis and erythrocytosis, allowing reduction in the requirement for phlebotomies within a few months. In both diseases, an objective hematologic response was observed in about 80% of patients, including complete freedom from phlebotomies in PV in 60% of patients. However, toxicity associated with IFN-α therapy was not trivial, leading to the discontinuation of treatment in almost 25% of patients. A pegylated form of IFN has been used with increasing frequency to treat patients with a variety of MPNs with great success. This form of IFN can be administered once weekly, and its use is associated with a more favorable toxicity profile. Several phase II studies using peg-IFNα-2a in PV and ET showed similarly impressive hematologic response rates compared with standard IFN-α, but with less associated toxicity (<10% of patients discontinued therapy during the first year of therapy). In addition, these studies showed for the first time evidence of significant molecular responses, as documented by a clear reduction in the *JAK2V617F* allele burden after IFN-α treatment. Overall, the two clinical trials with peg-IFNα-2a showed a meaningful and progressive reduction in the *JAK2V617F* allele burden in about 70% of PV and 40% of ET patients. Importantly, the *JAK2V617F* mutation became undetectable (with 1% sensitivity PCR assays) in 24% of PV patients in the French PVN-1 study after about 3 years' median follow-up, and in 14% and 6% of PV and ET patients, respectively, in the United States study after about 2 years' median follow-up. Combining both studies, 12 out of 64 (19%) PV patients achieved a molecular complete response (MCR). Of note, many of these MCRs occurred after the 12th month of treatment, but hematologic responses occurred within a few weeks. Prolonged exposure (>12 months) to peg-IFNα-2a seems to be an important factor in achieving MCR. The reduction in the *JAK2V617F* allele burden was not influenced by the cumulative dose of peg-IFNα-2a in the PVN-1 study, but toxicity was clearly dose dependent in the United States study. Taken together, these results indicate that peg-IFNα-2a therapy is best initiated at very low doses that are gradually increased until hematologic response is achieved; this strategy avoids cessation of therapy and allows sufficient exposure to the drug to allow for the achievement of a molecular response. These results are in agreement with studies from Denmark showing major molecular responses in PV after long-term treatment with IFNα-2b that could persist after IFN-α was discontinued. Finally, several who achieved MCR in the PVN-1 study have maintained this response after peg-IFNα-2a was discontinued (≤30 months after discontinuation), with none experiencing hematologic relapse. Such long-term clinical and molecular responses after the discontinuation of treatment have previously been reported after IFN-α therapy in MPN patients, an effect that has not been reported with other currently available therapies. It is important to emphasize that the elimination of *JAK2V617F* in this setting is not necessarily indicative of cure of the MPN, and that clinical implications of these molecular responses remain uncertain and require validation. It has been shown that molecular relapse can rapidly occur after IFN-α discontinuation in some cases. In one patient with a biclonal *JAK2V617F*/*TET2*-mutated PV, peg-IFNα-2a treatment did not affect the *TET2*-mutated cells, but the *JAK2V617F* clone was eradicated. Nevertheless, prolonged periods of time (≤40 months, personal unpublished data) during which the patient remained in complete hematologic remission without any cytoreductive therapy after peg-IFNα-2a withdrawal was observed in several patients of the PVN-1 study even though low levels of the *JAK2V617F* allele (≈5%) were still detected. Such results suggest that despite the disease not being eradicated, long-term exposure to peg-IFNα-2a was sufficient to modify the clinical expression of the MPN for a sustained period of time.

Recently, the results of randomized trials comparing the peg-IFNα-2a to HU in first-line treatment were published. In the MPD-RC-112 phase III trial high-risk untreated ET/PV patients were randomized to either peg-IFNα-2a or HU. The overall response rate was similar with 78% in peg-IFNα-2a group and 70% in HU group at 12 months and 91% and 88%, respectively at 24 months. Molecular responses were achieved in 11% of peg-IFNα-2a patients and 20% of HU patients. Best BM responses occurred in 17% of peg-IFNα-2a patients and 33% of patients treated with HU. More adverse events were reported in peg-IFNα-2a (41.9% >grade 3) arm compared to HU (24.4% >grade 3) arm. In a phase III DALLIAH trial 205 previously untreated patients were randomized to IFN alfa-2a, IFN alpha-2b, or HU. Interim analysis showed 49% overall response rate in MPN patients compared to 75% response rate seen with HU. It has been demonstrated that optimal response rates achieved with IFN can take a long time, so longer follow-up is needed to truly establish final response rates. In a second-line trial of peg-IFNα-2a in PV and ET patients that were resistant or intolerant to HU (MPD-RC 111), the ORR in the PV cohort at 12 months was 60%, and 22% of patients experienced CHR. The median absolute reduction in JAK2V617F allele burden was -6% (range −84% to 47%). Drug discontinuation related to AEs occurred in 13.9% of subjects.[50]

In addition to clinical, hematologic, and MCRs achieved in a significant proportion of PV patients, IFN-α therapy has also been shown recently to reverse BM histopathologic abnormalities in selected cases of both PV and PMF. Thus, IFN-α seems to be a drug able to deplete PV stem cells, and induce complete resolution of all clinical, biologic, and morphologic abnormalities in selected MPN patients, raising the hope that a curative outcome might be possible in a limited subset of such patients. These observations lead one to question the validity of the current therapeutic strategies for PV and ET patients in which myelosuppressive therapy is exclusively used in subpopulations of patients at high risk for developing additional thrombotic events.

IFN is not a leukemogenic drug but it is also not an innocuous agent, necessitating careful follow-up of patients receiving such treatment. Initially, many patients experience flu-like symptoms, which are controllable with acetaminophen or aspirin. Such symptoms usually resolve spontaneously after several months of therapy. More serious side effects, including excessive suppression of blood counts, irritability, high fevers, severe asthenia, reversible lower extremity bilateral neuritis, retinopathy, hypothyroidism, depression, sarcoidosis, and left-sided heart failure have been reported and may require cessation of IFN-α therapy. Exacerbation of depression and other psychiatric manifestations are serious potential side effects of IFN, and it should probably not be used in patients with history of clinically significant psychiatric conditions. Patients and family members should be counseled to watch for subtle evidence of depression, mood swings, and personality changes and to immediately report their concerns to the treating physician. The use of IFN should also be avoided in patients with any history of autoimmune diseases and new development of autoimmune disorders should be high on the differential diagnosis of patients being treated with any formulation of IFN.

Since a major limitation of peg-IFN is its toxicity profile and the need for weekly injections, a novel monopegylated interferon Ropeginterferon alpha-2b (ropeg) (PharmaEssentia) has already gained regulatory approval in the EU. It is administered every 2 weeks and with time even less frequently and its toxicity profile appears to be more favorable. The PROUD-PV study was a phase III registration study done in 48 clinics in Europe where 257 PV patients who were either treatment naive or had less than 3 years of HU treatment were randomly assigned to ropeg or HU. After 1 year of study, patients could opt to enter the extension part of the study, CONTINUATION-PV. At 12 months, Ropeg was shown to be non-inferior to HU at reaching the primary endpoint of complete hematologic response with normal spleen. In CONTINUATION-PV, complete hematologic response was met in 70.5% of patients in the ROPEG arm versus 51.4% of patients in the HU arm at 36 months (P=0.01). This difference was not apparent early on in the study when at 12 months of treatment CHR rates were 43% in the ROPEG arm and 46% in standard therapy arm. Over the 36-month treatment period, the proportion of patients who maintained their response was significantly higher in the ROPEG arm compared to the HU arm in terms of CHR as well as CHR with improved disease burden. Molecular responses in PROUD-PV were not significantly different between the two groups at 12 months. In both groups, a reduction in mean JAK2V617F allele burden compared to baseline was evident at 12 months. In the CONTINUATION-PV study, patients treated with ROPEG showed a steady decrease in the means absolute JAK2V617F allele burden to less than half the baseline level by month 36. However in the HU group the reduction was transient and was lost by month 36. Interestingly, Ropeg was relatively well tolerated with minimal grade 3 to 4 adverse events reported.[51] Jäger et al. performed a study of germline SNPs to identify those patients with the greatest potential to achieve MR with Ropeg therapy. They demonstrated a statistically significant effect at the interferon lambda 4 (*IFNL4*) locus diplotype (haplotype pair, including the protein-coding variants rs368234815/rs117648444) on MR as reflected in differential *JAK2*V617F mutational burden changes according to *IFNL4* diplotype status. These investigators showed that the absence of IFNL4 increased the chance of developing a MR. They proposed that a personalized approach to the use of Ropeg based upon IFN4 genotype/phenotype in patients with PV based on IFNL4 functionality might allow for the identification of patients most likely to benefit from Ropeg therapy.[52]

The reduction of JAK2 mutation VAFs by Ropeg therapy has led several investigators to propose that such therapy was capable of altering the natural history of PV thereby reducing the risk of additional thrombotic events as well as reducing the risk of progression to MF and MPN-BP. Unfortunately the effects of HU and Ropeg on these outcomes in the CONTINUATION-PV study were similar. Perhaps with longer follow-up such effects on alteration of the natural history of high-risk PV will be observed but at present these claims must be considered speculative. Recently this optimistic outlook for Ropeg therapy led to a randomized phase II trial of 100 low-risk PV patients randomized to receive either Ropeg every 2 weeks or phlebotomy alone. Ropeg was shown to be capable of reducing the phlebotomy requirements by only 15% as compared to 3% in the phlebotomy group.[53] Although this study was stopped by the data safety and monitoring committee prematurely due to the meeting of the primary endpoints, the clinical significance of these results are questionable. To answer the fundamental question of whether Ropeg is indeed capable of influencing the natural history of low-risk PV patients, the follow-up of the treated patients would have to be extended for a decade or two in order to accumulate enough events to determine the strength of this claim.

The use of small-molecule inhibitors of JAK1/2 ruxolitinib was first approved in the United States in 2011 for the treatment of advanced forms of MF, and in 2015 was approved for the treatment of patients with PV who were intolerant or resistant to HU. In a phase III study (RESPONSE trial), HU resistant or intolerant patients were randomized to receive either ruxolitinib or standard care. To be eligible for the study entry patients had to have splenomegaly with a spleen volume of at least 450 cm^3 and ongoing phlebotomy requirements, and be resistant to or intolerant of HU according to the standardized criteria. Standard care was selected by the investigator and included HU. Patients receiving standard therapy were able to cross over to ruxolitinib if they failed to achieve the primary end point by 32 weeks. The primary end point was achievement of hematocrit control and reduction in spleen size (at least 35% by MRI). This was achieved in 21% of patients in the ruxolitinib arm versus 1% of patients in the standard therapy arm. Hematocrit control was achieved in 60% of patients receiving ruxolitinib and 20% of patients receiving standard therapy, and 38% of patients in the ruxolitinib arm met the reduction in spleen end point versus 1% of patients in the standard therapy arm. By week 80, almost 60% of patients treated with ruxolitinib had normalization of their platelet counts. Patients on ruxolitinib enjoyed improvement in such PV-related symptoms as pruritus, headaches, fatigue, and night sweats. The mean change in *JAK2V617F* allele burden from baseline to week 32 was 12.2% in the ruxolitinib group and 1.2% in the standard therapy group. Based on an analysis after 80 weeks of follow-up, there was a suggestion that those patients receiving ruxolitinib had a reduced incidence of serious thrombotic events but that ruxolitinib therapy did not affect progression to MF and MPN-BP; these conclusions are not well substantiated since the study was not powered to examine these events. It also did not provide information on correction of the BM histopathological findings and chromosomal abnormalities in patients treated with ruxolitinib. In general, ruxolitinib was well tolerated with 85% of patients remaining on ruxolitinib at 81 weeks. The most common nonhematological adverse event was diarrhea, while the hematological toxicity included anemia, lymphopenia, and thrombocytopenia. In addition, the rates of nonmelanoma skin cancer were higher in the ruxolitinib arm compared with those patients receiving standard therapy. An increase in infectious complications was observed on ruxolitinib treatment, specifically herpes zoster infection. This has also been observed in MF patients treated with ruxolitinib. Cases of tuberculosis activation, toxoplasmosis, and other atypical infections have been reported in ruxolitinib-treated patients. The increased number of infections has been attributed to the inhibition of both T- and NK-cell function by ruxolitinib. Recently, a 5-year follow-up analysis of RESPONSE trial as well the RESPONSE 2 where the participating patients lacked splenomegaly on entry became available.[54] The majority of patients remained on the drug and maintained their clinical response at 5 years. Still conclusions could not be made regarding the effect of ruxolitinib therapy on the risk of progression to MF or MPN-BP or the risk of thrombosis. In the era of COVID-19 the use of ruxolitinib therapy presents some challenges. In a retrospective study of 175 MPN patients infected with the COVID-19 virus from clinical centers throughout Europe, ruxolitinib was used more frequently in patients who died than those who survived. Multivariable analysis, however, did not suggest any effect of ruxolitinib on mortality, but rather demonstrated an increased risk of death in patients who discontinued ruxolitinib treatment. These data indicate that PV patients treated with ruxolitinib should remain on this JAK1/2 inhibitor during the period of infection with the virus.

A recent phase II trial looked at the combination of INF-α2 and ruxolitinib in patients with PV and MF. The rationale for the combination was to target the malignant clone early and prevent clonal evolution and progression. In addition, the investigators raised the possibility that by decreasing inflammation, ruxolitinib might improve IFN signaling. This was a multicenter single arm study done in Denmark. Patients were treated with low-dose IFN and ruxolitinib ranging from 5 to 20 mg twice daily. After 2 years of treatment, of 32 patients with PV, 10 (31%) achieved a remission, of which 3 (9%) achieved complete remission. Overall improvements in total symptom score were also reported. The median *JAK2V617F* allele burden decreased from 47% to 12%, and 41% of patients achieved a molecular response. Total dropout rate was 16%. The majority of patients required a dose reduction of at least one drug. This is an interesting approach and further studies are clearly needed. The use of this combination drug therapy is associated with a high degree of myelosuppression and other overlapping toxicities from these drugs.[55]

Pruritus in PV patients occurs on exposure to sudden body cooling, especially after a warm bath, and is experienced by as many as 40% to 60% of patients treated with phlebotomy. The onset of pruritus may occur prior to the diagnosis of PV or at later time points following the diagnosis. In some studies, basophils and mast cells have been shown to be involved with *JAK2V617F* in patients with aquagenic pruritus and PV, likely leading to the elaboration of mediators that lead to itching. The frequency of pruritus appears to be somewhat lower in patients treated with myelosuppressive agents. This observation is related to the probable relationship between pruritus and degranulation of tissue mast cells and circulating basophils. Aged transgenic mice expressing *JAK2V617F* suffer from pruritis and the massive accumulation of mast cells in the skin. Cultured mast cells from these mice exhibited enhanced proliferative signals, relative resistance to cell death upon growth factor deprivation, and a growth advantage over control cells under suboptimal growth conditions. A JAK inhibitor was shown to reduce mast cell numbers and alleviate pruritus in *JAK2V617F* transgenic mice. Some uncontrolled studies have attributed pruritus to hyperhistaminemia or severe iron deficiency, with relief associated with the use of histamine antagonists or ferrous sulfate. Iron replacement is frequently not possible because it can lead to dangerous elevations of the RBC mass. In a number of instances, however, minimal iron replacement can be possible with disease control with cytoreductive therapy. The association between pruritus and tissue infiltration by mast cells would appear to explain the response of occasional patients to photochemotherapy with psoralens and ultraviolet irradiation. In addition, in one small study, 80% of patients with pruritus have been reported to respond to the selective serotonin uptake inhibitors paroxetine or fluoxetine. Other effective options include anticonvulsant drugs such as pregabalin. Ruxolitinib in both PV and PMF has a remarkable effect on reducing the severity of intractable pruritus. Ruxolitinib is much more effective in treating this particular symptom of PV compared with both HU and IFN and has become the treatment of choice for this particular symptom of PV. In occasional patients this effect, unfortunately, is not sustained.

Budd-Chiari syndrome (BCS) is a catastrophic illness that can lead to significant morbidity and mortality in patients with PV. Patients with MPN are at a high risk of developing this syndrome. Independently, the use of oral contraceptive pills and congenital and acquired thrombophilic factors are involved in its development. A number of cases of hepatic vein thrombosis have been reported in nonpolycythemic women taking oral contraceptives.

The optimal approach to the problem of BCS is obviously preventive and involves maintenance of normal blood values in the patient with PV. When BCS develops, the prognosis without treatment is dismal. The goals of therapy are to prevent further propagation of thrombus, relieve the intense hepatic congestion, and manage the severe ascites that often plague these patients. If untreated, these patients often have a slowly progressive course, with deterioration and death occurring within 3.5 years. Spontaneous resolution of the hepatic vein occlusion rarely occurs. There are no prospective randomized trials of anticoagulation in BCS, but retrospective studies suggest a survival benefit. Anticoagulation should be continued indefinitely unless there is a contraindication such as bleeding esophageal varices. Typically, low-molecular–weight heparin (LMWH) is used as the initial treatment with subsequent switch to warfarin. New direct acting oral anticoagulants (DOACs) that act by direct thrombin or factor Xa inhibition are being increasingly used for various prophylactic and therapeutic indications, and their use for these patients is becoming more widespread due to ease of administration and reversal agents are now available for some of these agents. However, evidence for efficacy and safety of using these agents in this setting is extremely limited. The use of DOACs in MPNs patients is discussed in greater detail in Chapter 71. The use of thrombolytic therapy directly in the thrombosed vein is infrequent due to the lack of data and potentially high risk of bleeding. Angioplasty with or without the use of stents attempts to restore hepatic blood flow and is often used if anticoagulation is not successful, and should be considered if liver function is deteriorating despite therapeutic anticoagulation. The overall success rate is about 95%, with a low periprocedural complication rate. The clinical deterioration of patients with BCS results from damage to the hepatocytes from necrosis associated with marked elevation in sinusoidal pressure coupled with ischemia from reduced hepatic arteriole perfusion. The only rational therapeutic intervention, therefore, involves some sort of portal vein decompression to achieve an effective reduction of sinusoidal pressure. Portosystemic shunting such as transjugular intrahepatic portosystemic shunt (TIPS) has been used extensively to treat refractory portal hypertension. Recent data show good long-term outcomes when using TIPS, and it is now considered standard management if anticoagulation or angioplasty are not successful, or if patients have high-risk disease. It has been shown that about a third of patients with BCS require TIPS placement. One-year survival in a recent large UK single-center study was 97% and 5-year survival 72%. Procedure-related complications are frequent but mortality rates are low.

Liver transplantation is a potential option for treatment of PV BCS patients with continued hepatic decompensation. The indications for liver transplantation are cirrhosis, fulminant hepatic failure, and failure of a portosystemic shunt. The overall actuarial survival at 1 year was 76% and was 68% at 10 years. Because PV is a slowly progressive disease, transplantation should not be withheld from these patients. Pretransplant predictors of mortality based on a multivariable analysis were impaired renal function and a history of a shunt. The hematologic consequences of polycythemia must be aggressively treated in the posttransplantation setting; hepatic vein occlusion may reoccur in the transplanted liver.

Therapy of CVT and sinuses includes anticoagulation with heparin to arrest the thrombotic process and to prevent pulmonary embolism. LMWH should be started as soon as the diagnosis is confirmed even in the presence of hemorrhagic infarcts. After the acute phase, life-long oral anticoagulant therapy is recommended. There is currently no available evidence from randomized clinical trials regarding the efficacy or safety of thrombolytic therapy. Many patients also receive long-term myelosuppressive therapy with HU, ruxolitinib, or pegylated forms of IFN. De Stefano however recently reported that HU does not prevent reoccurrences of splanchnic vein thromboses in MPN patients,[56] while Mascarenhas failed to observe a single rethrombosis in the same patient population with pegylated IFN therapy.[57] Based on this limited data we usually maintain such patients of pegylated IFN in order to normalize blood counts in a sustained manner.

The performance of any surgical procedures on patients with PV is, as previously discussed, accompanied by excessively high morbidity and mortality. Elective surgery should not be contemplated unless the patient's hematologic values have been normalized for several months. The longer the hematologic control has been in effect, the lower the incidence of postoperative complications. If emergency surgery is required, the patient should be phlebotomized rapidly until a normal hematocrit is reached, and platelets should be available in case excessive perioperative or postoperative bleeding occurs. After emergency or elective surgery, the patient should be mobilized as soon as possible, and strong consideration should be given to anticoagulation with LMWH unless the patient has some contraindication. Dental extractions can also result in excessive hemorrhage and should not be performed unless the patient is under strict hematologic control.

Perhaps the most difficult and frustrating period encountered during the clinical course of a patient with PV is the development of post-PV MF. The origins, manifestations, and management options are discussed in detail in Chapter 72.

Limited information is available concerning the treatment of patients who develop MPN-BP after PV. The overwhelming majority of such cases involve myeloid leukemias. The leukemia is frequently preceded by post-PV MF but not always. Patients with post-PV MF and MPN-BP frequently have greater than 20% blasts in the peripheral blood but far fewer blast cells in the BM, which has led to a hypothesis that the leukemia originates from an extramedullary site, particularly the spleen. These cases tend to have a more indolent course, but patients with a greater degree of BM infiltration have a more highly proliferative form of leukemia that is associated with an even more aggressive course. The optimal treatment of such patients is unknown. In elderly adults with significant comorbidities, the choice not to institute chemotherapy is a reasonable option. These patients are frequently elderly, and poor results with standard regimens have been reported. Patients rarely achieve a complete remission but rather return to a clinical condition that resembles their original MPN for limited periods of time. In a retrospective analysis on 23 patients with leukemic transformation of PV, the median patient age was 68 years, and MPN-BP developed a median of 12.8 years from the diagnosis of PV. Twelve of the 14 patients in whom cytogenetic analyses were performed had complex cytogenetic abnormalities associated with high-risk leukemias. Fifteen patients were treated with palliative measures and had a median survival of 2.5 months. Of the eight patients treated with standard induction therapy, one obtained a complete remission, and seven died without obtaining a response. The median survival time of these chemotherapy-treated patients was 5.6 months. The median survival time of the entire cohort of 23 patients was 2.9 months. This poor outcome is likely the result of clinical and biologic features of the acute leukemia, advanced patient age, unfavorable cytogenetics, and patient comorbidities associated with advanced age. Selected patients are likely to tolerate and have a favorable outcome with allogeneic stem cell transplantation and reduced-intensity conditioning. In fact, the only long-term survival with post-PV leukemia has been observed in patients receiving allogeneic stem cell transplantation. For eligible patients, remission induction should be attempted using either standard AML induction therapy or combination of DNA hypomethylating agents (HMA) with or without the bcl 2 inhibitor venetoclax. Once remission is achieved patients should proceed to transplant as soon as possible. Promising results with the use of HMAs such as decitabine or azacitidine alone or in combination with ruxolitinib have been reported, with 50% to 60% of patients achieving clinically significant responses persisting for 6 to 24 months in the majority of cases. More recently the use of bcl-2 inhibitor venetoclax has changed the landscape of AML treatment as it has shown remarkable efficacy in combination with HMAs. The data for the use of venetoclax in AML secondary to MPN is mixed. Gangat and coworkers in a multicenter trial of a HMA plus venetoclax reported a CR rate of 44% versus 4% with a HMA alone. Most importantly, this combination successfully allowed many patients to move forward with allogenic stem cell transplantation.[58] These chemotherapeutic regimens can frequently be administered as an outpatient but require treatment for multiple monthly cycles before clinical responses can be evaluated. Recently we have begun to treat these patients with oral decitabine with impressive outcomes. Although many of these patients do not achieve true complete remissions, their prolonged survival and quality of life, at least based upon single-institutional studies, appears to be superior to that achieved with standard induction chemotherapy.

PV occurs frequently during childbearing years. A discussion of contraception options is imperative because the use of oral contraceptive pills may be associated with an increased risk of deep venous thrombosis as well as splanchnic vein thrombosis. It seems prudent to entertain alternative forms of contraception with such individuals. Discontinuation of HU in both men and women desiring to have a child is recommended. HU is capable of inducing azoospermia in men, frequently limiting their ability to father a child. Pregnancy is itself a prothrombotic condition. PV in a pregnant individual has been reported to lead to an increased incidence of fetal demise, with up to 30% of pregnancies in PV patients terminating in spontaneous abortions. In addition, preeclampsia occurs more frequently in these women. A team approach requiring close communication between an obstetrician skilled in providing care for high-risk pregnancies and the responsible hematologist provides the optimal integration of care to the mother and the child. Pregnancy in PV patients is frequently associated with a gradual normalization of blood values, and it is not unusual for a woman who has required extensive therapy for control of her disease to no longer require phlebotomies during pregnancy. Delivery appears not to be complicated by excessive hemorrhage, but the postpartum period carries an increased risk of venous thrombosis. Although some degree of hematocrit level normalization can be explained by expansion of the plasma volume or by nutritional deficiencies that occur during pregnancy, it is unlikely that these factors can be solely responsible. It seems more reasonable to assume that the high estrogen levels characteristic of pregnancy suppress erythropoiesis. After completion of the pregnancies, the patients' hematologic values slowly drift back to their previously elevated values in parallel with the return to normal estrogen levels. Because pregnancy is usually associated with spontaneous control of the polycythemic state, no specific therapy is required except for careful observation. If needed, therapy should be limited to phlebotomy and low-dose aspirin therapy because of the mutagenic effects of chemotherapeutic agents. Aggressive treatment of hypertension is imperative, as well as attention to the risk of developing preeclampsia and toxemia, which should be treated in a standard fashion. In individuals with a history of repeated spontaneous abortions associated with placental infarction, consideration should be given to low-dose aspirin with LMWH therapy, making sure that these agents are discontinued at the time of delivery to avoid the risk of excessive hemorrhage. If this approach is not successful, IFN therapy is suggested because it is not known to be leukemogenic or teratogenic and does not cross the placenta. In the puerperium, thromboprophylaxis with 6 weeks of LMWH therapy or a DOAC is recommended. Aggressive intervention with hematocrit levels maintained below 45% and aspirin therapy with LMWH is associated with a positive outcome for the pregnancy. Breastfeeding is recommended if the mother is receiving therapy with heparin or Coumadin as long as the baby receives adequate supplementation with vitamin K. Rapid mobilization of the mother after delivery is of great importance.

Because PV is ultimately a stem cell disorder, it should be possible to achieve a cure with stem cell transplantation. Thus far, the majority of patients undergoing allogeneic stem cell transplantation have been transplanted after evolution to MF, MDS, or acute leukemia. Transplantation during the polycythemia phase of the disease is at present not appropriate.

FUTURE DIRECTIONS

The discovery of *JAK2V617F* mutations has led to a more comprehensive understanding of the pathophysiology of the MPNs, including PV. There is no question that the diagnostic tests for *JAK2V617F* and exon 12 mutations of *JAK2*, as well as mutations in *VHL*, *HIF-1*, *HIF-2*, the *EPOR*, and *PHD* have revolutionized the diagnostic approach to patients with erythrocytosis. PV is a stem cell disease that will ultimately require curative therapies at a minimum to deplete or eliminate malignant stem cells if curative small-molecule therapies are to become a reality. Although the *JAK2V617F* VAF has been used as a biomarker for outcomes of novel therapeutic approaches to treat patients with PV, studies are needed to determine the extent of reduction of allele burden that would be predictive of altering the natural history of PV and eliminating complications from thrombotic episodes or evolution to MF or MPN-BP. The use of drugs affecting only JAK2 is unlikely to be curative because multiple genetic and epigenetic events likely contribute to the origins and progression of PV. Randomized clinical trials of combinations of drugs, rather than single drugs, and comparing these outcomes with the standard of care are more likely to lead to significant advances in improving the natural history of PV patients. The use of novel immunotherapeutic approaches as well as strategies to interrupt the TPO/MPL axis should serve as new therapeutic platforms to develop novel therapeutic strategies.

CHAPTER 71

ESSENTIAL THROMBOCYTHEMIA

Bridget K. Marcellino, John Mascarenhas, Camelia Iancu-Rubin,
Marina Kremyanskaya, Vesna Najfeld, and Ronald Hoffman

Essential thrombocythemia (ET) is a chronic myeloproliferative neoplasm (MPN) characterized by platelet counts in excess of 450 × 10^9/L, profound bone marrow (BM) megakaryocyte hyperplasia, leukocytosis, splenomegaly, a clinical course punctuated by hemorrhagic and/ or thrombotic episodes, and a possible evolution to myelofibrosis (MF) and MPN blast phase (MPN-BP). ET is a clinically heterogeneous disorder, with more than half of patients meeting the criteria for diagnosis being asymptomatic at presentation. ET is associated with the clonal acquisition of driver mutations (*JAK2*), the thrombopoetin receptor (*MPL*), or calreticulin (*CALR*) that activate the JAK-STAT signaling pathway, allowing hematopoiesis to occur in the absence of exogenous cytokines. The *JAK2*V617F mutation occurs in 50% to 60% of ET patients, while recurrent *CALR* mutations occur in 15% to 24% of patients. Finally, about 3% to 5% have *MPL* mutations. The ET patients who lack such driver mutations but have histomorphologic features diagnostic of ET are referred to as being “triple negative.” ET was first described in 1934 by Epstein and Goedel, reporting on a patient with an elevated platelet count who had repeated hemorrhagic episodes.

EPIDEMIOLOGY

The true incidence of ET is unknown because extensive epidemiologic studies are not available. The incidence of ET has been estimated to be approximately 1.5 to 2.4 patients per 100,000 populations annually. A Swedish study indicated that first-degree relatives of patients with an MPN, including ET, had a five- to sevenfold increased risk of developing an MPN, supporting the concept that there is a strong genetic predilection. ET occurs in individuals with a median age of 67 to 73 years. To gain additional insight into the patterns of occurrence of MPNs by age, sex, race/ethnicity, and susceptible populations and provide a population-based assessment of patient survival, Srour et al.[1] used data from the Surveillance, Epidemiology, and End Results (SEER) Program of the National Cancer Institute in the United States, to better assess the incidence of MPNs in the United States from 2001 to 2012. Importantly, during a part of this period of time, the use of mutational analyses in making the diagnosis of MPNs became widespread. There were 31,904 MPN cases diagnosed among residents of the 18 SEER registries evaluated. The age-adjusted incidence rates (IRs) were as follows: polycythemia vera (PV; 10.9 per 1 million patient years), ET (9.6), chronic myeloid leukemia (CML; 3.3), and primary myelofibrosis (PMF; 3.1). ET was the only MPN with a significantly lower IR among males than females; the average age at diagnosis was 68 years. The female predominance was most pronounced in individuals less than 60 years of age. Surprisingly, the IR of ET was 18% higher among Blacks than among non-Hispanic Whites; ET was associated with a female predominance among non-Hispanic Whites, White Hispanics, Blacks, and Asian–Pacific islanders, suggesting shared gender-specific risk factor(s) across these racial/ethnic groups. A recent study compared the impact of sex on MPNs and found that male sex was an independent predictor of a poorer overall survival and higher rate of progression to MF and MPN-BP which might be attributable to their having higher *JAK2*V617F variant allele frequencies (VAF) as well as an increased number of acquired non-MPN specific myeloid malignancy gene mutations (*ASXL1*, *EZH2*, *SRSF2*, *U2AF1*, and *IDH1/2*).

The incidence patterns observed by Srour et al.[1] support inherent differences in susceptibility to developing an MPN. This study was of importance since it represented the first step in appreciating the potential for molecular diagnostics to improve our understanding of the epidemiology of the MPNs. Recent studies have confirmed that in addition to the *JAK2*V617F mutation, mutations in *CALR* and *MPL* are also key drivers of this disease. These data suggest that ET is a relatively common hematological malignancy that has an especially significant impact on younger women due to their propensity to develop venous thromboses.

There are shared susceptibility genes that predispose individuals to develop MPNs. The Janus kinase 2 (*JAK2*) mutations (V617F) are not acquired randomly but arise preferentially on a specific *JAK2* haplotype (46/1). The *JAK2* 46/1 haplotype has been shown not only to predispose *JAK2*V617F-positive ET but also to ET harboring *MPL* and *CALR* mutations, again indicating that genetic factors play a role in the susceptibility to developing ET. Tapper et al. also identified additional two single-nucleotide polymorphisms (SNPs), r14339666 within *JAK2* and rs2201862, 153 kb downstream of the DS1 and EVI1 complex locus protein EVI1 (*MECOM*), which were associated with *JAK2*V617F-negative MPNs. Two additional SNPs, rs2736100 in telomerase reverse transcriptase (*TERT*), and rs9376092 between *HBS1L* and *MYB*, were associated with *JAK2*V617F-positive MPNs. The SNP between *HBS1L* and *MYB*, rs9376092, however, had a stronger effect on MPNs associated with *CALR* and/or *MPL* mutations, whereas in *JAK2*V617F-positive cases, rs9376092 was associated with ET rather than PV. These investigators demonstrated that the candidate risk allele at rs9376092, which had a strong association with ET, was associated with reduced *MYB*. Prior functional analyses have shown that mice expressing low levels of MYB develop a transplantable ET-like disease. These findings indicate that multiple germline variants predispose to the development of each of the MPNs and link constitutional differences in *MYB* expression, in particular to ET. Additionally, germline mutations in ET patients have been shown to affect their clinical course. For instance, ET patients with a specific SNP variant in the ERCC2 gene have nearly a fourfold higher risk of progressing to MPN-BP.

ET has rarely been reported in the pediatric age group. The incidence of ET in childhood has been reported to be approximately 1 per 10^7 population, which is 60 times less than that in adults. Approximately 30% of children with this disorder experience thrombotic or hemorrhagic complications at diagnosis or later in their course, and 50% have splenomegaly. Mutations in one of the established MPN driver genes, *JAK2*, *CALR*, or *MPL*, were present in a lower percentage of pediatric cases (34%), compared with adult MPN patients (90%). The subgroup of patients without a detectable driver mutation tended to have higher platelet counts, compared with patients with mutations. One must always exclude inherited disorders that are known to lead to isolated thrombocytosis before being certain that a child who lacks a known driver mutation has ET.

Several families with multiple members having ET have been described. The prevalence of the *JAK2*V617F mutation in familial cases of MPN has been analyzed in 72 families, including 174 patients (68 with ET). The *JAK2* mutation was found in half of patients with ET and a similar proportion as observed in sporadic, nonfamilial cases. Among 46 families with at least two cases of PV, ET, or PMF, the *JAK2* mutation was absent in six families, heterogeneously distributed in 18, and present in all patients with MPN in 22. Thus, the *JAK2* mutation does not seem to be required for the development of ET or other MPNs, and this familial clustering cannot be accounted for by the prevalence of the *JAK2* 46/1 haplotype. In familial MPNs, *CALR* mutations can also be somatically acquired and are associated with an ET or PMF phenotype.

PATHOBIOLOGY

ET is a clonal hematological malignancy originating at the level of the hematopoietic stem cell. The thrombocytosis that characterizes ET is caused by increased platelet production due to increased numbers of megakaryocytes. Effective platelet production is increased as much as 10-fold and is associated with an increase in megakaryocyte clustering, volume, nuclear lobe number, and nuclear ploidy.

Although ET originates at the level of the pluripotent hematopoietic stem cell, a significant proportion of nonclonally derived leukocytes exist, in addition to the clonally derived population of leukocytes in patients with ET. In one study of 42 patients with ET, 31 patients exhibited clonality of at least one hematopoietic lineage, but the remaining 11 patients had a polyclonal origin of all the lineages studied. The biogenesis of polyclonal ET remains a subject of investigation. Interestingly, in some patients, monoclonality of hematopoiesis is restricted to platelets, despite the polyclonal origin of cells belonging to other lineages. Presently it is possible that some patients with polyclonal triple negative thrombocytosis cases might have ET, which might be missed since the *JAK2*V617F VAF in such a case is higher in platelet RNA than in granulocyte DNA, which is routinely used for the performance of mutational analyses. Therefore it is important to directly perform WES or whole-genome sequencing on megakaryocytes or to sequence platelet RNA in order to establish the diagnosis and the presence of clonality in such triple negative ET cases. Alternatively, the isolated thrombocytosis in such cases of presumed polyclonal triple negative ET could be due to diseases other than MPNs, particularly hereditary forms of thrombocytosis associated with germline gain-of-function mutations in *JAK2* and *MPL or reactive causes of thrombocytosis*. In addition, another type of polyclonal ET has also been reported in patients with a *CALR* mutation. Two *CALR* frameshift mutation-positive patients were reported with an oligo-clonal disease: one patient had one clone that was positive for a *CALR* type-1 mutation and a second clone possessed a *CALR* type-2 mutation, while the second patient had separate clones that were positive for either *JAK2*V617F or a *CALR* type-2 mutation.

Increased numbers of megakaryocyte progenitor cells are present in the BM and the peripheral blood of patients with ET. These data support the concept that the principal abnormality is an expansion of the progenitor cell pool. In addition, progenitor cells were noted to either be hypersensitive, or independent of the addition of exogenous cytokines, including interleukin (IL)-3, IL-6, and thrombopoietin. A second subpopulation of colony-forming unit–megakaryocyte (CFU-MK) assayed from patients with ET remained dependent on the addition of exogenous cytokines.

Mutational Spectrum in Essential Thrombocythemia

The hypersensitivity of ET progenitor cells to a variety of cytokines is due to the clonal acquisition of driver mutations (*JAK2*, *MPL*, or *CALR*) that activate the JAK-STAT signaling pathway, allowing hematopoiesis to occur in the absence of exogenous cytokines. The *JAK2*V617F mutation occurs in 50% to 60% of ET patients, while recurrent *CALR* mutations occur in 15% to 24% of patients, and 3% to 5% have *MPL* mutations. The patients with ET who lack such driver mutations are said to be "triple negative." While the driver mutations were originally thought to be mutually exclusive, it has recently been identified that a small subset of ET patients with low VAF *JAK2*V617F can have co-occurring *CALR* or *MPL* mutations.

JAK2 is a cytoplasmic tyrosine kinase that plays a key role in mediating intracellular signaling from a variety of growth factors, including IL-3, erythropoietin, granulocyte-macrophage colony-stimulating factor (GM-CSF), granulocyte colony-stimulating factor (G-CSF), and thrombopoietin. Co-expression of *JAK2*V617F with a homodimeric type 1 cytokine receptor (including erythropoietin, thrombopoietin, or G-CSF) is necessary for hormone activation of JAK-STAT (signal transducer and activator of transcription) signaling pathways and for hematopoietic cell proliferation to become growth factor–independent. The *JAK2*V617F mutation is present in ET patients with both clonal and polyclonal hematopoiesis. Patients with clonal hematopoiesis have a higher *JAK2*V617F allele burden (26%) than patients with polyclonal hematopoiesis (16%). The relative size of the *JAK2V617F* clone is often small and remains stable over time in patients with both clonal and polyclonal ET. A VAF higher than 50% indicating the presence of granulocytes, homozygous for *JAK2*V617F, has been found in 70% of PV patients, but occurs less frequently in ET. In ET patients, the increase in the *JAK2*V617F VAF from a level well below 50% at presentation, to a level above 50% after years of follow-up could be indicative of the imminent evolution of the patient's ET to PV. All PV patients have assayable erythroid colonies that are homozygous for *JAK2*V617F, even in PV patients with a low burden of *JAK2*V617F. By contrast, hematopoietic colonies cloned from ET patients are only occasionally *JAK2*V617F homozygous colonies. The transition from *JAK2* heterozygous to homozygous progenitors is a consequence of homologous recombination. These studies suggest that such an event is characteristic of PV but rarely occurs in ET. If there is a substantial increase in the numbers of *JAK2*V617F homozygous progenitors in an ET patient, it would likely lead to a transition from an ET to a PV phenotype.

STATs are activated downstream of *JAK2*V617F. STAT3 is a pivotal regulator of megakaryocytopoiesis, which might provide an explanation for its exclusive upregulation in ET. To further examine the differences between hematopoiesis in *JAK2*V617F ET and PV, the gene expression profiles of *JAK2*V617F-heterozygous erythroid colonies have been examined. Erythroblasts from ET patients were characterized by enhanced expression of genes associated with interferon (IFN) signaling and phosho-STAT1, compared with PV erythroblasts. STAT1 is essential for IFN-γ signaling. Increased STAT1 in normal CD34$^+$ cells has been shown to favor megakaryocytic differentiation but reduce erythroid differentiation, creating a differentiation pattern that resembles ET. Furthermore, inhibition of STAT1 signaling in ET hematopoietic progenitor cells led to enhanced erythropoiesis and reduced megakaryocytopoiesis. These studies suggest that in ET, *JAK2*V617F induces the simultaneous activation of STAT5 and STAT1 pathways, but in PV, the relatively reduced levels of phospho-STAT1 reduce the brake on erythropoiesis. Further functional annotation analyses have also demonstrated that clusters of gene ontology terms related to inflammation, immune system, apoptosis, RNA metabolism, and secretory system are also significantly dysregulated terms in ET, PV, and MF. These data support the concept of MPNs being a biological continuum transitioning from ET to PV to PMF.

Thrombopoietin is the primary physiologic regulator of thrombopoiesis, which acts by binding to its cell surface receptor, MPL. Thrombopoietin levels in a normal individual are inversely related to megakaryocyte mass. MPL is expressed by CD34$^+$ hematopoietic stem and progenitor cells, MKs, and platelets. One would anticipate that thrombopoietin levels in ET would be low due to the characteristic megakaryocytic hyperplasia. Normal or slightly elevated thrombopoietin levels have, however, been observed in patients with ET. Furthermore, Wang et al. have reported that thrombopoietin levels were significantly higher in patients with ET than in patients with reactive thrombocytosis who had similar levels as control. This unanticipated elevation of thrombopoietin levels in ET patients might be explained by the observation that the expression of the thrombopoietin receptor and its mRNA is dramatically reduced in the platelets of patients with ET. Thrombopoietin serum levels are controlled by platelet mass through MPL-mediated thrombopoietin uptake and degradation. The reduced platelet MPL expression occurs not only in ET but also in PV and PMF and has been shown to be a downstream event of *JAK2*V617F, which promotes the proteasomal degradation of MPL. The reduced MPL likely results in the decreased capacity of platelets to absorb thrombopoietin, contributing to the increased megakaryocyte mass and thrombocytosis. The mutations in the thrombopoietin receptor, *MPL*W515L and *MPL*515K, are present in approximately 3% to 5% of patients with ET, and additional novel *MPL* mutations have been identified in ET patients in a recent study utilizing deep mutational scanning of MPNs and will require further investigation. About 60% of patients with *MPL* mutations have the W515L mutation and 40% have the W515K mutation. The mutant allele burden is greater than 50% in 50% of W515K patients compared with 17% of W515L patients. The most prevalent *MPL* mutations in ET occur on tryptophan 515, an amino acid that maintains MPL in an inactive form in the absence of cytokines. Rarely, in ET patients, another *MPL* mutation, S505N, serves as a driver mutation. It is located in the exon 10 domain that encodes the transmembrane domain of MPL and induces dimerization of the transmembrane helix in an active confirmation. The *MPL* mutations occurring in ET trigger conformational changes in the receptor, bringing into close proximity two molecules of bound JAK2, for transphosphorylation and activation of the JAK-STAT signaling cascade. The loss of tryptophan, but not the acquisition of a particular residue, induces the constitutive activation of MPL. In ET, both *JAK2*V617F and *MPL* mutations arise preferentially on a specific constitutional *JAK2* 46/1 haplotype. Two hypotheses have been proposed to account for this predilection: 46/1 is inherently genetically more unstable (hypermutability hypothesis) or 46/1 confers a growth advantage that favors the predominance of *JAK2*V617F hematopoiesis (fertile ground hypothesis). The association of *MPL* mutations with the *JAK2* 46/1 haplotype strongly favors the hypermutability hypothesis rather than the fertile ground hypothesis. The presence of *MPL*W515K mutations in ET patients is associated with lower hemoglobin levels and higher platelet counts, as well as preferential expansion of the numbers of megakaryocytes at the expense of erythroid precursors, as observed in BM biopsy specimens.

Of patients with ET or MF who do not have mutations in *JAK2* or *MPL*, the overwhelming majority have a mutation in *CALR*. Mutations in the *CALR* gene occur in 15% to 24% of ET patients and rarely occur together with mutations of *JAK2* or *MPL*. The clinical phenotype of patients with *JAK2*-mutated and *CALR*-mutated ET differs. The presence of the mutated *CALR* is associated with a younger age, male predominance, higher platelet counts, lower hemoglobin levels, lower leukocyte counts, and a lower risk of thrombotic complications. Recent studies have suggested that the lower thrombotic rates in *CALR*-mutated ET may in part be due to reduced leukocyte activation or less reactive platelets, compared with their *JAK2*V617F-positive counterparts. *CALR*-mutated ET patients do not evolve to PV while this transition occurs in 20% to 30% of *JAK2*V617F+ ET patients over a 15-year period. Grinfeld et al. have independently reported that *CALR* mutations are independently associated with an increased risk of developing MF.[2]

The wild-type *CALR* gene encodes for an evolutionarily conserved, multifunctional protein, involved in multiple cellular processes ranging from calcium homeostasis and protein folding in the endoplasmic reticulum, to apoptotic cell death clearance and cellular adhesion. The *CALR* mutations (*CALR*: 19p13.2) identified in MPN mainly consist of deletions (i.e., type I) or insertions (i.e., type II) occurring within exon 9, which create a novel epitope in the C-terminal domain of the protein. Despite the heterogeneity of these mutations, the new C-terminus sequence is identical and results in the loss of the KDEL domain, which is critical for CALR retention in the endoplasmic reticulum and its ability to regulate calcium homeostasis. Original studies describing *CALR* mutations in MPN indicated that such a uniform defect may confer a proliferative advantage to malignant cells via activation of the JAK-STAT pathway.

Mutations of *CALR* are very rare in PV but are found in patients with MF and ET, the two MPN entities in which megakaryocytic hyperplasia is a hallmark of the disease. The most frequent *CALR* mutations, accounting for more than 80% of the total, are the type-1 variant, a 52 bp deletion (p.L367fs*46), and the type-2, a 5 bp TTGTC insertion (p.K385fs*47). The other types of mutations have been observed at much lower frequencies, and many have been detected only in individual patients. Overall, type-1 is more frequent (53%) than type 2 mutations (31.7%), but the incidence of type-2 mutations is higher in ET as compared to MF. Type 1 mutations are more frequent in MF patients. Some investigators have conjectured that type 1 *CALR* mutations are a forme fruste of MF. Most *CALR* mutations are present in a heterozygous state, although rare patients are homozygous for *CALR* mutations, which are associated with uniparental disomy of chromosome 19p. The *CALR* mutations target the hematopoietic stem cell and the mutation can be detected in granulocytes, monocytes, platelets, B, and NK cells. Occasionally in ET patients, they may be seen in T cells. Both types of *CALR* mutations lead to an increase in the number of megakaryocyte progenitors that are hypersensitive to cytokines. A series of subsequent reports have shed light on the mechanisms responsible for the ability of the mutated *CALR* to induce MK hyperplasia and thrombocytosis in MPN. Thus four independent laboratories have demonstrated that the oncogenic activity of mutated *CALR* is mediated by MPL, which is critical for both hematopoietic stem cell and megakaryocytic lineage development. Thus mutant *CALR* expressed by hematopoietic cells in vitro or in vivo in mouse models binds and activates MPL but not other type I hematopoietic cytokine receptors. This, in turn, leads to JAK-STAT pathway activation, resulting in the development of thrombocytosis and an ET-like phenotype. Interestingly, in vivo overexpression of either of the mutation variants (type I, deletion; or type II, insertion) induces thrombocytosis and constitutively activates MPL and JAK-STAT signaling. Yet, while type II mutations favor MK proliferation, type I mutations confer clonal dominance of the hematopoietic stem cell, resulting in splenomegaly, BM hypocellularity, and fibrosis, a phenotype reminiscent of "post-ET" MF. These findings mirror the clinical observations in which type I mutations are more prevalent in MF patients, while type II mutations are more frequent in ET patients. Moreover, CD34$^+$ hematopoietic progenitors from ET patients harboring the type II *CALR* mutation are capable of forming spontaneous CFU-MK, validating the initial suggestions that the mutated *CALR* confers cytokine-independent cell growth.

Elegant molecular and biochemical studies dissecting the interaction between mutant *CALR* and *MPL* and its downstream consequences revealed that the N-glycosylation sites of the MPL extracellular domain are required for its activation by mutated *CALR* and are independent of the thrombopoietin binding site. Furthermore, the mutated *CALR* translocates to the cell surface and acts in an autocrine manner by binding and activating MPL. Recently, it has been postulated that the interaction between mutant CALR and MPL may occur in the endoplasmic reticulum. Although the exact mechanisms by which the mutated CALR binds to the MPL are under investigation, preliminary evidence suggests that the oncogenic properties of the mutated CALR can be attributed to the positive electrostatic charge of the novel peptide, which may be responsible not only for the physical interaction with MPL but also for other cellular functions involving the normally negatively charged portion of the protein

(Fig. 71.1). Mutated *CALR* can also affect the immune system. When CALR is present on the cell surface, it acts as an "eat me" signal that facilitates the recognition of stressed cells by phagocytes that express the CALR receptor, CD91. This type of innate immune response facilitates the transfer of tumor antigens to dendritic cells, thereby facilitating the induction of cancer-specific cytotoxic T cells. The mutated CALR proteins escape from the ER system and can be secreted into the tissue microenvironment. Liu et al.[3] have reported that soluble CALR proteins can, in fact, act as decoy receptors, preventing the uptake of CALR-expressing cells by dendritic cells, thereby leading to profound immunosuppression. *CALR* mutations may therefore play two roles in ET and MF (1) activating cell autonomous oncogenic drivers and (2) blunting the immune response. In fact, immune suppressive mechanisms, including T-cell exhaustion, have been reported in patients harboring mutant *CALR*, perhaps due to its effects on the dendritic cell activation reported above. This immune suppressive effect of CALR-mutated proteins has been proposed as the reason why *CALR*-mutated MPNs arise 10 years earlier than *JAK2*V617F+ MPNS. Mutant *CALR* has recently been proposed as an MPN-specific neoantigen that might serve as a target for immunotherapeutic approaches. CALR-specific T-cell responses have been partially restored in vitro and in vivo by antibodies directed against immune checkpoint inhibitors. The success of such vaccine strategies, however, might require the development of strategies directed towards restoring immune responses in patients by overcoming the effects of secreted mutated CALR.

The SH2B adaptor protein 3 (SH2B3) gene, also known as the *LNK* gene, encodes a negative regulator of cytokine signaling. Occasional cases of ET are associated with loss-of-function *LNK* (SH2B3) mutations. In mouse models, the inhibitory adaptor protein, LNK, has been shown to be associated with the downmodulation of erythropoietin and thrombopoietin signaling. LNK can bind to wild-type *JAK2*, *JAK2*V617F, wild-type *MPL*, and *MPL*W515L. Lnk levels are upregulated and they correlate with an increase in the *JAK2*V617F VAF in MPN patients. In *JAK2*V617F-positive ET, LNK mRNA expression is upregulated and serves to modulate *JAK2*V617F-mediated cell regulation. Thrombopoietin-mediated signaling regulates LNK expression at both the mRNA and protein levels. Furthermore, acquired *LNK* mutations have been observed in less than 1% of ET. The inactivating *LNK* mutations in ET patients result in JAK-STAT activation, leading to high levels of STAT3 and STAT5 activation. Cabagnois and coworkers used whole-exome sequencing and next-generation sequencing, targeting *JAK2* and *MPL*, with the intent of detecting additional mutations in triple negative ET patients. They found several signaling mutations, including *JAK2*V617F with very low VAFs, as well as additional mutations such as: *LNK* mutation, *MPL*-S505N, *MPL*-W515R, and *MPL*-S204P. *MPL*-S204P and *MPL*-Y591N were shown to be weak gain-of-function mutants, increasing MPL signaling and conferring either thrombopoietin hypersensitivity or independence to expressing cells, but with low efficiency. These data demonstrate that some clonal, noncanonical *MPL* gain-of-function mutations are associated with triple negative cases of ET. "Triple negative" ET patients have also been shown to harbor clonal markers involving other myeloid associated genes, including ten–eleven translocation (*TET2*) and *KIT*. In addition, a recent study showed that nearly a quarter of those ET patients diagnosed as "triple negative" actually harbored low-level *JAK2* or *MPL* mutations, detected using deep next-generation sequencing. The study also revealed that "true triple negative" ET patients and ET patients with known driver

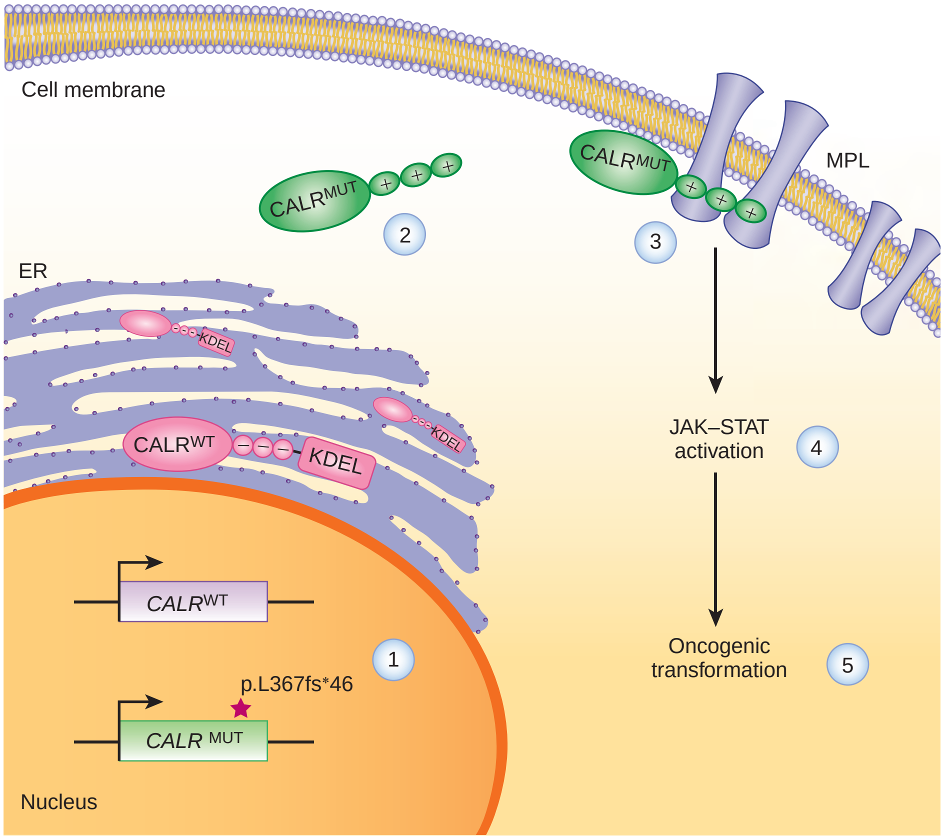

Figure 71.1 SCHEMATIC REPRESENTATION OF THE POTENTIAL MECHANISM OF ACTION OF MUTATED CALRETICULIN. Deletions (type I mutations) or insertions (type II mutations) occurring in the exon 9 of *calreticulin (CALR)* gene (1) result in a novel epitope in the C-terminus of the protein which lacks the endoplasmic reticulum (ER)–retention signal (KDEL) and is positively charged compared with the negatively charged wild-type protein (2). The mutated *CALR* is capable of binding thrombopoietin receptor (MPL) (3), which, in turn, activates the Janus-activated kinase–signal transducer and activator of transcription (JAK-STAT) signaling pathway (4), thus providing proliferative advantage of the malignant clone (5). *(From Stanley RF, Steidl U. Molecular mechanism of mutant CALR-mediated transformation. Cancer Discov. 2016;6(4):344–346.)*

mutations had similar gene expression profiles consistent with activation of the JAK/STAT and nuclear factor kappa B (NFkB) pathways.[4] Ultimately, patients with triple negative ET cannot always be classified as having an MPN and should be evaluated for inherited forms of thrombocytosis.

Mutations in epigenetic regulators (such as *TET2*, *DNMT3A*, *ASXL1*, *EZH2*, and isocitrate dehydrogenase [*IDH*]*1*/*IDH2*) and in spliceosome components (such as *SRSF2*, *U2AF1*, and *SF3B1*) have been shown to be present in MPN patients with *JAK2*/*MPL*/*CALR* mutations. Other mutations were also directly associated with leukemic progression, such as *TP53*, *RUNX1*, *CBL*, and deletion in *IKAROS*. Several of these mutations can occur in the same patient, and most frequently *SRSF2* can occur with *TET2*, *ASXL1*, or *IDH* mutations. In contrast to *MPN* driver mutations, which are rare in other myeloid malignancies, these additional mutations are not specific to MPNs and are found with a higher frequency in patients with myelodysplastic syndrome (MDS) and in MDS/MPN overlap syndromes, such as chronic myelomonocytic leukemia (see Chapter 73) as well as AML. Biologic studies and mouse models have shown that these additional mutations may cooperate with *MPN* driver mutations to favor clonal dominance (*TET2* or *DNMT3A*), to modify disease phenotype, or to promote either progression to MF or leukemic transformation (*ASXL1*, *IDH1/2*, *EZH2*, and *TP53*). Tefferi and coworkers have reported that the percentage of ET patients with 1, 2, or ≥3 sequence variants/mutations was 41%, 8%, and 4%, respectively, with the most frequent sequence variants/mutations in *TET2* and *ASXL1*. In addition, a significant association between the MPN driver mutational status and the number or type of other sequence variants/mutations in the Mayo Clinic series of 183 patients with ET was not observed. Especially important was their stratification of survival by the presence or absence of "adverse" (*SH2B3*, *IDH2*, *SF3B1*, *U2AF1*, *EZH2*, *TP53*) or "other" (*TET2*, *ASXL1*, *PTP11*, *SUZ12*, *ZRSR2*, *CBL*, *CEBPA*, *CSF3R*, *DNMT3A*, *SRSF2*, *FLT3*, *KIT*, *NRAS*, *RUNX1*, *SETBP1*) sequence variants/mutations. Those patients in a cohort of 174 Italian patients with ET, with adverse mutations, had a median survival of 18.4 years as compared to 29 years for those individuals who harbored other vatiants that were not high-risk.[5] A recent study evaluating the genomic profiles of ET and PV patients who undergo leukemic transformation revealed that *DNMT3A*, *U2AF1*, *IDH1*, *IDH2*, and *EZH2* mutations were associated with early transformation (median time to transformation 3 years) and *TP53*, *BCORL1*, and *NRAS* mutations were associated with late transformation (median time to transformation 21 years).[6]

The *TET2* gene encodes a hydroxylase that is able to hydroxylate methylated cytosine. These mutations result in a loss of function, leading to increased DNA methylation and a reduction in hydroxymethylcytosine. *TET2* mutations occur in 11% of ET patients. Mutations in *TET2* can occur either before or after mutations of *JAK2* or *MPL*. Mutations in the gene for IDH occur in 0.9% of ET patients and can functionally lead to similar effects as *TET2* mutations on DNA methylation. Furthermore, disrupting mutations of *ASXL1*, which occur in 36% of PMF patients, are infrequent in ET, as are mutations of *CBL* or *EZH2*.

Furthermore, the transcription factor NFE2 has been shown to be overexpressed in the cells of patients with MPNs independent of the presence or absence of *JAK2*V617F. The NFE2 acts as an epigenetic transcriptional regulator and a chromatin modifier. It is part of a complex regulatory network, including transcription factors such as GATA1 and RUNX1, controlling megakaryocytic and/or erythroid cell function. The knockout mouse model displays only mild erythroid abnormalities, while the major phenotype is a defect in megakaryocyte biogenesis. Indeed, the absence of NFE2 leads to severely impaired platelet production. Genetically engineered mice that overexpress NF-E2 are characterized by extreme thrombocytosis and leukocytosis, normal hemoglobin levels, and BM hypercellularity, which is a clinical picture similar to that observed in ET patients. Frameshift and deletion *NFE2* mutations are found in approximately 2% to 4% of ET patients and have been shown to be preferentially associated with *MPL* (30%) and *CALR* (40%) mutations.[7] While there was no direct correlation between *NF-E2* and *JAK2*V617F VAF in different MPNs, the frequency of *NFE2* mutations resulting in a functionally enhanced truncated form of *NF-E2* was doubled in patients with greater than 50% VAF (9.7% vs. 4.1%). Furthermore, Grinfeld and coworkers reported that the presence of *NF-E2* mutations was correlated with the transition of *JAK2*V617F+ ET patients to a PV phenotype. Mice expressing *NF-E2* mutations develop erythrocytosis and thrombocytosis due to the expansion of their progenitor and stem cell compartments, and in the long term may develop leukemias with concomitant and/or isolated myelosarcoma. Marcault and coworkers reported that MPN patients with *NF-E2* mutations with VAFs greater than 5% were at an increased risk of transformation to MPN-BP.

Thrombosis and Hemorrhage in Essential Thrombocythemia

The cause of the increased risk of developing hemorrhagic and thrombotic events, associated with ET, remains the subject of investigation. The following increase the risk of thrombotic complications in ET: age greater than 60 years, a history of a thrombotic event, the *JAK2*V617F mutation, leukocytosis (>11,0000/L), and the presence of cardiovascular risk factors, including tobacco use, hypertension, or diabetes mellitus. Hemorrhagic events occur almost exclusively in individuals with extremely high platelet counts ($>1000 \times 10^9$/L).[8] Extreme thrombocytosis is most common in young females. Although anxiety-provoking for many practicing hematologists, extreme thrombocytosis in an otherwise low-risk patient is not thought to be associated with a greater risk of developing thrombotic episodes. Thrombosis-free survival has been reported to be similar between patients presenting with or without extreme thrombocytosis and the development of arterial and venous thromboses were similar in patients with and without extreme thrombocytosis.

The incidence of thrombotic events in ET patients ranges from 1.5% to 6.6% per patient-year. Age-related differences in the frequency of thromboses have been attributed to the coexistence of vascular disease in older patients. The thrombotic events in ET are largely arterial, but venous thromboses also occur. Patients with *JAK2*V617F+ ET compared with those with a *CALR* mutation or those who are triple negative have a higher risk of developing thrombotic events, but a dose-dependent correlation between allele burden and the development of clinical symptoms has not been demonstrated. Recent data show that the *CALR*-type 2 mutation, but not the type 1 mutation, is protective against thrombosis when compared to *JAK2*V617F. Recently, Eaton and coworkers have provided data that indicate that JAK2 plays a role in primary hemostasis, affecting thrombus formation by facilitating platelet adhesion and spreading on collagen by altering collagen receptor GPV1 signaling. These data suggest that the enhanced risk of thrombosis in *JAK2*V617F+ ET patients might be a consequence, in part, of this continued enhanced platelet GPV1 signaling.

Many investigators have struggled to identify ET patients who are at the greatest risk of developing thrombotic episodes. A thrombotic scoring system has been developed by investigators on both sides of the Atlantic.[9] In the latest iteration of this risk stratification schema, four categories were delineated: very low-risk (no thrombosis history, age ≤60 years, and *JAK2*-unmutated); low-risk (no thrombosis history, age ≤60 years, and *JAK2*-mutated); intermediate-risk (no thrombosis history, age >60 years, and *JAK2*-unmutated) and high-risk (thrombosis history, age >60 years, and *JAK2* mutation). The use of aspirin in low-risk patients is debated and treatment of *CALR*-mutated ET patients with aspirin did not affect the risk of thrombosis but was associated with a higher incidence of bleeding.[10] How to personalize therapy based upon such a schema remains problematic and to date untested.[11]

Some progress has been made in defining the relationship between platelet numbers and the risks of thrombotic and hemorrhagic events in ET. In a randomized trial of patients at a high-risk of developing a thrombotic event (>60 years of age, a history of a thrombotic episode, or both), the reduction of platelet numbers was highly effective

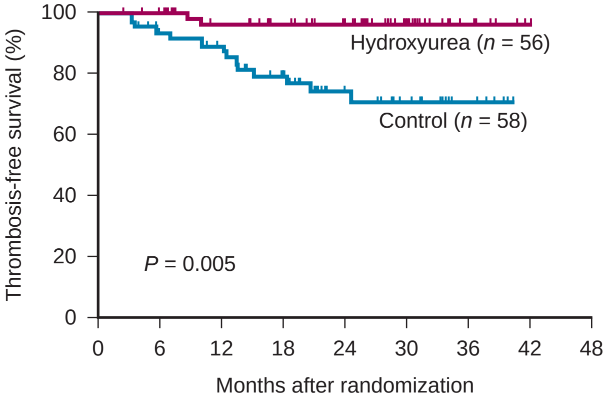

Figure 71.2 PROBABILITY OF THROMBOSIS-FREE SURVIVAL IN 114 PATIENTS WITH ESSENTIAL THROMBOCYTHEMIA TREATED WITH HYDROXYUREA OR LEFT UNTREATED. *(From Cortelazzo S, Finazzi G, Ruggeri M, et al. Hydroxyurea for patients with essential thrombocythemia and a high risk of thrombosis. N Engl J Med. 1995;332:1132.)*

in preventing additional thrombotic events (Fig. 71.2). Furthermore, the incidence of thrombotic events has been shown to be closely correlated with the duration of thrombocytosis in a case–control study. Unfortunately, there has been difficulty in defining what particular target platelet count should serve as an endpoint for myelosuppressive therapies to maximally reduce the degree of thrombotic risk. Many investigators have provided data that indicate that interactions between platelets and activated leukocytes participate in the thrombotic risk of ET patients, suggesting to some that normalization of leukocyte numbers should also be a therapeutic endpoint.

Several groups have confirmed that the degree and duration of bleeding in ET patients is correlated with platelet numbers. The clinical spectrum of bleeding in ET patients closely resembles that observed in von Willebrand disease. Several groups have now shown that high platelet counts ($>1000 \times 10^9$/L) are associated with an acquired form of von Willebrand syndrome, and that reduction of platelet numbers is associated with correction of the von Willebrand syndrome-like abnormalities and cessation of bleeding episodes. The mean platelet count in patients with ET and acquired von Willebrand disease is $2050 \pm 1107 \times 10^9$/L. An increase in the number of circulating platelets appears to favor the adsorption of larger von Willebrand multimers onto platelet membranes, resulting in their removal from the circulation and their subsequent degradation.

Platelets in patients with ET have been known, for a considerable time, to be qualitatively abnormal. Although both increased and decreased platelet reactivity have been described, these findings have not been definitively associated with thrombohemorrhagic complications, with two noteworthy exceptions—erythromelalgia, in which the prompt relief of symptoms by cyclooxygenase inhibitors provides direct evidence that prostaglandins play a role in the development of vascular occlusion, and acquired von Willebrand syndrome, which is a major cause of bleeding in patients with ET.

Abnormal platelet aggregation has been reported in 35% to 100% of patients with ET. The majority of such studies have used conventional platelet aggregation studies performed on platelet-rich plasma. The simultaneous measurement of platelet aggregation and adenosine triphosphate–dense granule release by whole-blood platelet lumiaggregometry has been used to study platelet function in ET patients with the hope of identifying patients at risk of developing thrombosis. A prospective analysis of large cohorts of patients has not been performed to confirm the utility of such assays. Platelets derived from patients with ET and PV have been shown to contain a large proportion of immature platelets that have been recently released from the BM. Such immature platelets have increased hemostatic activity, as demonstrated by a heightened response to thrombin and greater expression of P-selectin. Hydroxyurea has been shown to be capable of reducing the number of immature platelets in ET, which might partly be responsible for the reduced thrombotic risk associated with its use.

Abnormal aggregation studies have not been successful in predicting the incidence of episodes of hemorrhage or thrombosis. In ET, platelet aggregation is classically defective in response to epinephrine, adenosine diphosphate (ADP), and collagen but is usually normal with arachidonic acid and ristocetin. Characteristically, in ET, the first wave of aggregation is diminished, and the second wave of aggregation is absent in response to epinephrine. Interestingly, preincubation of ET platelets with thrombopoietin partially corrects the impaired aggregation in response to epinephrine, ADP, and collagen. An acquired form of platelet storage pool disease occurs frequently in ET. Platelet α-granule content and the release of the content of granules are abnormal, resulting in elevated plasma levels of platelet factor-4 and β-thromboglobulin.

Numerous individual functional platelet abnormalities have been demonstrated. A defect in the metabolism of arachidonic acid by lipoxygenase has been documented, as have decreased numbers of platelet receptors for prostaglandin D_2 and adrenergic receptors for epinephrine. Platelets from patients with thrombotic episodes have been found to be capable of increased generation of thromboxanes and to have an increased affinity for fibrinogen. Elevations in β-thromboglobulin and serum thromboxane levels in ET patients are validated indices of enhanced in vivo platelet activation and possibly thrombin generation. Such abnormalities are not present in patients with secondary thrombocytosis and may provide some explanation for the high incidence of thrombosis associated with ET. The antithrombotic activity of aspirin has been attributed to its ability to permanently and selectively inactivate platelet cyclooxygenase-1 (COX-1) and thereby block thromboxane biosynthesis. This action has served as the rationale for the widespread use of aspirin in ET patients for thrombosis prophylaxis in the absence of valid controlled clinical trials. COX-2 has been shown to be overexpressed by the megakaryocytes and platelets of ET patients; it can also contribute to the enhanced biosynthesis of thromboxanes in ET. Low-dose aspirin can only partially correct this enhanced thromboxane synthesis, likely because of the increased COX-2 activity associated with the increased rate of platelet generation associated with ET, providing the rationale for the use of more aggressive aspirin scheduling or the addition of thromboxane receptor A_2 antagonists to reduce the incidence of thrombotic events. Although laboratory data indicate a rationale for twice-daily dosing of aspirin, prospective clinical data for this approach are lacking.

The platelet activation observed in ET has also been linked to Src, which is a nonreceptor tyrosine kinase particularly abundant in platelets. In thrombin-stimulated platelets, Src kinase is required for platelet aggregation. This preactivation of Src that is characteristic of ET and the related platelet hyperactivity is likely to account for the hypercoagulable state that is emblematic of ET. In vitro studies also implicate *JAK2*V617F-driven heparinase overexpression in ET as a novel thrombotic mechanism. Heparinase has previously been shown to complex and enhance the activity of tissue factor, resulting in activation of the coagulation cascade.

Microvascular thrombosis causing digital or central nervous system ischemia leads to a variety of clinical syndromes closely associated with ET. The survival of platelets in ET patients with erythromelalgia and thrombosis has been shown to be reduced. Thrombosis in this setting is associated with an increased platelet turnover. Treatment of erythromelalgia with aspirin increased mean platelet survival from 4.0 ± 0.3 days to 6.9 ± 0.4 days and was associated with a significant elevation of platelet numbers. These findings suggest that erythromelalgia results from platelet-mediated thrombosis of the arterial microvasculature of the extremities. Complete correction of this ischemic circulatory defect is associated with the use of platelet cyclooxygenase inhibitors, such as aspirin and indomethacin. Agents that do not inhibit platelet cyclooxygenase, such as coumadin, sodium salicylate, dipyridamole, sulfinpyrazone, and ticlopidine, are not active in the treatment of this disorder.

One intriguing explanation for the increased risk of thrombosis in patients with ET has been the observation that the total amount of thrombin generated on the platelet surfaces of patients with ET is markedly greater than that generated on the platelet surfaces of normal control participants or patients with reactive thrombocytosis. The molecular basis of this abnormality has not been defined. Increased numbers of platelet microparticles, as well as increased platelet–neutrophil and platelet–monocyte complexes, have been observed in patients with ET. Platelet microparticles support thrombin generation and leukocyte activation. Increased numbers of platelet microparticles have been associated with the development of vascular thrombosis.

In vivo leukocyte activation has been shown to occur in ET and to be associated with signs of activation of both the coagulation cascade and endothelial cells. Such platelet and leukocyte activation may play a role in the generation of the prethrombotic state that characterizes ET. Interestingly, the presence of the *JAK2* mutation is associated with a greater degree of platelet and leukocyte activation. Activated neutrophils are able to bind platelets, which triggers the expression of tissue factor, as well as endothelial cell activation and damage. From a clinical point of view, several studies have demonstrated that an increased leukocyte count (>11,000 × 10^9) in patients with ET is an independent risk factor for developing arterial thrombosis, especially myocardial infarction, and is associated with an inferior survival rate. Therefore, an important role for leukocytes in the pathogenesis of thrombosis in ET is becoming more evident. Direct involvement of endothelial cells of MPN patients by *JAK2*V617F has been reported by several groups, which might lead to endothelial dysfunction in subsets of MPN patients, further enhancing the thrombotic predisposition to the development of splanchnic vein thromboses.

CLINICAL MANIFESTATIONS

The presenting symptoms of patients with ET are quite variable. Many patients (12% to 67%) reach medical attention fortuitously as a result of the extreme degree of thrombocytosis detected when obtaining a routine blood cell count. Most patients present with symptoms related to small- or large-vessel thrombosis, or minor bleeding. The thrombotic events at diagnosis and during follow-up occurred at rates of 10% to 29% and 8% to 31%, respectively. In general, arterial events predominate over venous events. Presentation with a major bleeding episode is unusual. Neurologic complications are common. Table 71.1 lists representative neurologic complaints, of which headache was the most common, with paresthesias of the extremities a close second. There was an extremely high incidence of transient ischemic attacks involving both the anterior and posterior cerebral circulation. These attacks have a sudden onset, last for a few moments, and are frequently associated with a pulsatile headache. The various symptoms occur sequentially rather than simultaneously and can be preceded or followed by erythromelalgia. Transient neurologic symptoms include unsteadiness, dysarthria, dysphoria, motor hemiparesis, scintillating scotomas, amaurosis fugax, vertigo, dizziness, migraine-like symptoms, syncope, and seizures. The syndrome is caused by platelet-mediated ischemia and thrombosis in end-arterial microvasculature. It is not unusual for these symptoms to eventually progress to definitive cerebral infarcts.

TABLE 71.1 Frequency of Neurologic Complaints Associated With Essential Thrombocythemia

Manifestations	Patients *(n)*
Headache	13
Paresthesias	10
Posterior cerebral circulatory ischemia	9
Anterior cerebral circulatory ischemia	6
Visual disturbances	6
Epileptic seizures	2
Total number of patients	33

Data from Jabaily J, Iland HJ, Laszlo J, et al. Neurologic manifestations of essential thrombocythemia. *Ann Intern Med.* 1983;99(4):513–518.

Microvascular circulatory insufficiency involving the toes and fingers is frequent. Such events can lead to digital pain, enhanced by warmth; distal-extremity gangrene; and classic erythromelalgia. The term *erythromelalgia* refers to a syndrome of redness and burning pain in the extremities. Erythromelalgia, which is characterized by a burning pain and a dusky congestion of swollen extremities, is usually preceded by paresthesias. Cold provides relief from these symptoms, while heat intensifies them. Patients prefer to wear shoes or slippers without socks and elevate their feet. These symptoms may progress in intensity and lead to the peeling of skin in the affected appendages or affected toes or fingers, which then may become cold and ischemic, with a dark purplish tinge. Erythromelalgia symptoms are asymmetric in the majority of cases. Symptoms related to coronary artery disease or transient ischemic attacks may precede or accompany the onset of erythromelalgia. Occasionally, hemorrhagic episodes may occur in patients experiencing erythromelalgia. Platelet counts in patients with erythromelalgia are frequently below 1000 × 10^9/L. The relief of such pain for several days after a single dose of aspirin is diagnostic of erythromelalgia. The specific microvascular syndrome of erythromelalgia is readily explained by platelet-mediated arteriolar inflammation and occlusive thrombosis, leading to acrocyanosis and even gangrene. Skin biopsies from the affected sites reveal arteriolar lesions without involvement of venules, capillaries, or nerves. The arteriolar endothelial cells are swollen and the vessel walls thickened by cellular swelling and deposition of intracellular material. Compared with atherosclerotic circulatory obstruction, arterial pulses in patients with erythromelalgia remain normal. Other patients develop platelet-mediated acral inflammation and arterial thrombosis, which can progress to ischemic acrocyanosis or necrosis of fingers, toes, and, rarely, the tip of the nose (Fig. 71.3).

Although thrombosis of the microvasculature is generally more frequent, thrombosis of large veins and arteries in patients with ET still occurs commonly. Patient symptoms frequently occur related to large-vessel thrombosis, mostly in the arteries of the legs, the coronary arteries, and the renal arteries. Involvement of the carotid, mesenteric, and subclavian arteries is frequent, and patients characteristically have venous thromboses involving the splenic vein, hepatic veins, or veins of the legs and pelvis. Unexplained thrombosis of the hepatic veins leads to Budd-Chiari syndrome, and thrombosis of the renal vein can result in the development of nephrotic syndrome. Splanchnic vein thromboses occur predominantly in young women with ET. Patients with this complication are at a high risk of having poor survival because of hepatic failure or transformation to MF or acute leukemia. It is worth noting that a fraction of patients with idiopathic splanchnic vein thrombosis may present with normal or near-normal blood counts but have an occult MPN based on genetic or

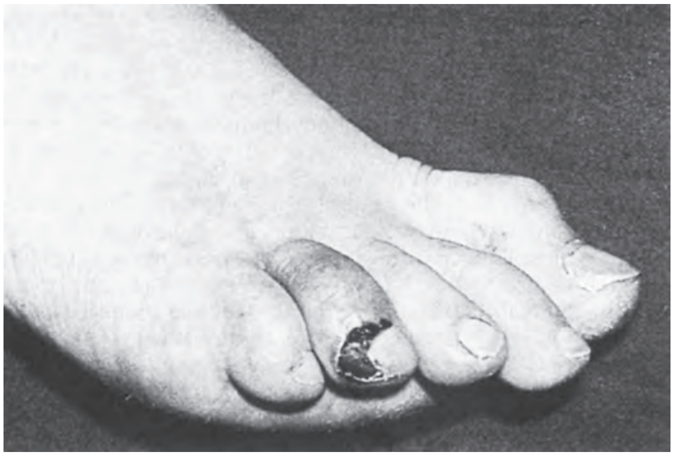

Figure 71.3 GANGRENE OF THE TOE IN A PATIENT WITH ESSENTIAL THROMBOCYTHEMIA.

histopathologic abnormalities. In a review of more than 800 patients with splanchnic vein thrombosis without a diagnosis of an MPN, a mean of 32.7% of patients were *JAK2*V617F-positive. More than 50% of these patients were subsequently diagnosed with an MPN. In addition, 2.6% of patients with cerebral sinus and vein thrombosis were also shown to be *JAK2*V617F-positive. These studies suggest that all cases of splanchnic vein thrombosis, likely cerebral sinus, and vein thrombosis should be tested for *JAK2*V617F to identify patients with an occult MPN. Occasional patients with idiopathic splanchnic vein thromboses with *CALR* mutations have been reported. In those patients who are *JAK2*V617F-negative, it is prudent to also search for *CALR* mutations. Priapism is a rare complication of ET, presumably caused by platelet sludging in the corpus cavernosum. In addition, myocardial ischemia and infarction associated with normal coronary angiograms have been reported in patients with ET, as has a high incidence of anginal symptoms. Acute renal failure has been observed after thrombosis of renal arteries and veins in patients with ET. Pulmonary hypertension, secondary to alveolar capillary plugging by platelets and megakaryocytes, has also been reported in patients with ET, with one meta-analysis reporting approximately 20% of ET patients having pulmonary hypertension.

Hemorrhagic events occur in 3% to 18% of patients with ET; the primary sites of bleeding are the gastrointestinal tract, mouth, nose, and throat. Other sites of bleeding may be the skin, eyes, urinary tract, tooth sockets (after extraction), joints, or brain. Nicol and coworkers reported that major bleeding episodes were relatively rare, ranging from 0.43 to 5.3 per 100 patient events. Central nervous system bleeds were the most frequent cause of fatal bleeds. A high incidence of bleeding episodes during the immediate postoperative period, including dental extractions, is likely caused by postsurgical thrombocytosis and the development of acquired von Willebrand syndrome or the use of antithrombotic prophylaxis therapy. Bleeding is closely correlated with a significant increase in platelet counts in excess of 1500 × 10^9/L and is associated with pseudohyperkalemia. It is important to emphasize that individual patients can experience both thrombotic and hemorrhagic episodes.

Appreciation of the risk of developing thrombohemorrhagic events in asymptomatic patients with ET who are younger than 40 years of age is imprecise at best. Such patients are thought to be at a low risk of developing thrombotic episodes, unless they have experienced a prior thrombotic episode or have associated cardiovascular risk factors. The most common thrombotic complications include migraine headaches in 20% of the patients and erythromelalgia in 5% of the patients. Life-threatening hemorrhagic episodes are rare. The degree of leukocytosis has been suggested by some investigators to be useful in discriminating between young patients with a low or high risk of developing a thrombotic episode.

A meta-analysis has revealed that the *JAK2*V617 mutation is associated with a twofold higher risk of developing either a venous or arterial thrombosis but does not influence the risk of suffering from a hemorrhagic event. Regardless, it is conceivable that the significantly more advanced age and elevated hematocrit and leukocyte levels in mutation-positive patients might contribute to the apparent association between *JAK2*V617F and thrombosis reported in some studies.

Patients with ET who are older than 60 years of age and who have had a prior thrombotic event have a greater risk of developing additional thrombotic events (Table 71.2). By contrast, the incidence of thrombotic and hemorrhagic complications in asymptomatic patients with ET who are younger than 60 years of age and who have platelet counts of less than 1500 × 10^9/L has been shown to be comparable to that of a normal control population. Gender, hypertension, diabetes mellitus, hypercholesterolemia, and smoking have been shown to be independent risk factors for developing arterial thrombotic complications in ET (see Table 71.2). Screening of patients for other acquired and inherited thrombophilic states may identify patients at an even higher risk for both arterial and venous thrombotic events.

Pregnancy is not contraindicated in patients with ET. The outcome of pregnancy in patients with ET has been the subject of intense investigation. The rate of having a successful pregnancy is 61%, compared with an 85% to 90% rate in normal women. The rate of spontaneous abortions ranges from 39% to 44%, compared with the miscarriage rate of 10% to 15% in normal pregnancies. Placental infarction is often responsible for intrauterine fetal growth retardation (5%). Abruptio placenta has been reported in 3.6% of cases, a rate that is higher than that observed in the general population (1%). Major thrombotic episodes occur in 3% of these pregnancies, while major bleeding episodes occur in 2% of cases. These rates are higher than those observed in the overall population of pregnant women. Baseline platelet count is not predictive of pregnancy outcome. ET patients with the *JAK2*V617F mutation have been reported to be at a higher risk of developing complications with pregnancy. In the postpartum period, the platelet counts return to their earlier levels, and rebound thrombocytosis may occur in some patients. This is thought to increase the probability of vascular complications during this period to a level similar to that observed in other conditions of thrombophilia.

TABLE 71.2 **Revised-IPSET Risk Stratification for Thrombotic Risk in ET Patients**

Risk Category	Age >60 Years	History of Thrombosis	*JAK2V617*-Positive
Very low	No	No	No
Low	No	No	Yes
Intermediate	Yes	No	Yes
High	Yes[a]	Yes[a]	Yes

[a]Either age >60 years or history of thrombosis.
ET, Essential thrombocythemia; *IPSET*, international prognostic score for essential thrombocythemia.
Data from Barbui T, Vannucchi AM, Buxhofer-Ausch V, et al. Practice-relevant revision of IPSET-thrombosis based on 1019 patients with WHO-defined essential thrombocythemia. *Blood Cancer J*. 2015;5(11):e369.

In the large majority of cases, the fetal losses in pregnant ET women occur during the first trimester. A previous history of spontaneous abortion may be the greatest risk factor for the development of subsequent spontaneous abortions.

Physical examination findings are relatively unremarkable in patients with ET. Most patients are not severely ill at diagnosis, with a median Karnofsky score of 90% being reported in one series. Splenomegaly is detectable in 40% to 50% of patients, and approximately 20% have hepatomegaly. During the course of the disorder, a further increase in the degree of hepatosplenomegaly may be observed in patients who are developing post-ET MF. Skin manifestations of the MPN have been reported to be relatively common, ranging from paraneoplastic lesions, including vascular, neutrophilic plaques, and unexplained dermatoses. Rarely, vascular changes result in microcirculatory flow abnormalities, leading to a vasculitis resulting in classic purpura that may progress to skin necrosis. This should be distinguished from leg ulcers that occur in patients being treated with hydroxyurea. Occasionally, patients also develop pyoderma gangrenosum or Sweet syndrome.

LABORATORY MANIFESTATIONS

The hallmark of ET is a sustained and unexplained elevation of the platelet count (≥450 × 10^9/L). Accompanying leukocytosis is a common finding. A leukoerythroblastic blood picture, as well as teardrop-shaped RBCs, are not features of ET but are suggestive of an early form of MF. Mild eosinophilia (>400/mm^3) and basophilia (>100/mm^3) have been reported in more than one-third of patients.

The most common morphologic abnormalities are variations in RBC size and shape and the presence of megathrombocytes (Fig. 71.4). The BM is usually normocellular or slightly hypercellular without

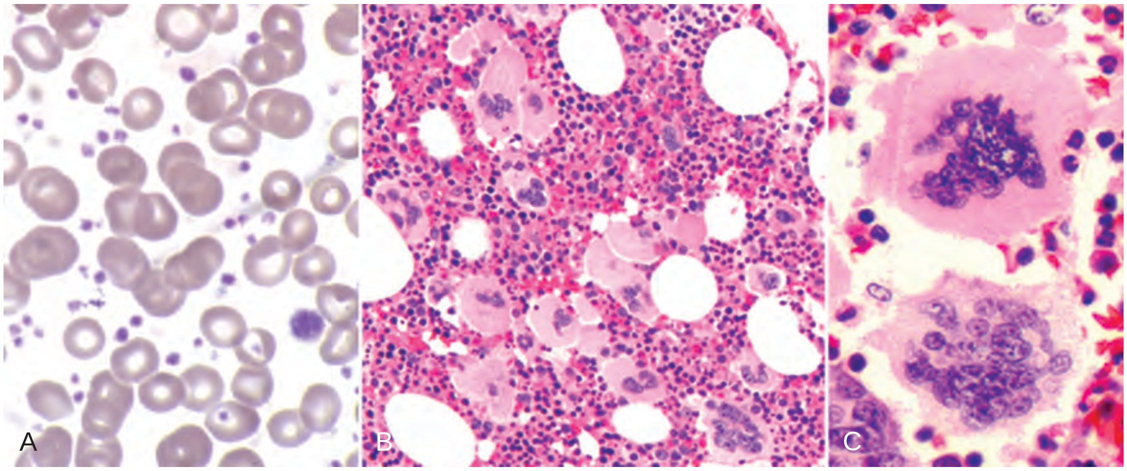

Figure 71.4 ESSENTIAL THROMBOCYTHEMIA: PERIPHERAL BLOOD SMEAR AND BONE MARROW BIOPSY. The peripheral blood smear in essential thrombocythemia (ET) shows a marked thrombocytosis with anisocytosis (varying sizes) of the platelets (A). The bone marrow (B) is hypercellular and exhibits a marked proliferation of large and giant megakaryocytes in loose clusters with other hematopoietic elements in the background. The large megakaryocytes (C) tend to be extensively lobulated.

a significant increase in granulopoiesis or erythropoiesis. Increased numbers of enlarged megakaryocytes with hyperlobulated or deeply folded nuclei that cluster in small groups along sinuses are the hallmarks of ET (see Fig. 71.4). Reticulin fibrosis is not significantly evident. A great deal of controversy currently surrounds distinguishing "true ET" from an early prefibrotic form of MF (pre-PMF), in which the BM is characteristically hypercellular with pronounced proliferation of granulocytes and reduced erythroid precursors. The megakaryocytes are increased in number but are loosely clustered or located along the endosteal bone surface. The megakaryocytes contain hyperchromatic, hypolobulated bulbous, or irregularly folded nuclei with an abnormal nuclear-to-cytoplasmic ratio. The histopathologic criteria for this form of pre-PMF have been combined with clinical criteria (minor criteria) by the World Health Organization (WHO). The 2016 criteria for the diagnosis of ET and pre-MF are particularly useful (Table 71.3). These new criteria are heavily dependent on mutational analyses. The *JAK2*V617F mutation occurs in 50% to 60% of ET patients, while recurrent mutations in *CALR* mutations occur in 25% of patients, and 3% to 5% have *MPL* mutations. Approximately 25% of patients harbor mutated *CALR* as either a type I (52-bp del) or type II (5-bp insertion). Investigators have claimed in a series which requires validation in a larger sample size that each driver mutation was associated with a specific morphological pattern in the BM.[12]

The patients with ET who lack such driver mutations are said to be "triple negative" (see Table 71.3). Based on the 2016 WHO Diagnostic Criteria, the presence of modest BM reticulin fibrosis does not exclude the diagnosis of ET. Although select hematopathologists can reproducibly distinguish ET from pre-PMF, it remains uncertain whether this distinction is broadly applicable. In 70% to 80% of ET patients, iron stores were present in the BM, albeit at reduced levels. Almost all patients have normal serum ferritin levels. The absence of iron stores in 30% of patients may merely be an epiphenomenon of a chronic MPN and not truly reflective of an iron deficiency state. Platelet aggregation study results are frequently abnormal and most often demonstrate an impaired aggregation response to epinephrine, ADP, and collagen but not to arachidonic acid and ristocetin. Spontaneous platelet aggregation has been reported to occur frequently in such patients, but this has not been a universal finding.

Approximately 25% of patients with ET have been reported to have elevated uric acid levels at diagnosis. The average value of the serum potassium at diagnosis is usually within the normal range, although 23% of patients have been reported to have pseudohyperkalemia, caused by the degranulation of platelets when in vitro clotting releases potassium. Both excessive numbers of RBCs and leukocytes can also be associated with these phenomena. Pseudohyperkalemia can be documented by measuring plasma instead of serum potassium levels and the lack of electrocardiographic findings associated with true hyperkalemia. Pseudohypoxemia has also been observed in ET patients with extreme degrees of thrombocytosis. Acquired von Willebrand syndrome is associated almost uniformly with a platelet count greater than 1500×10^9/L, a prolonged bleeding time, normal factor VIII coagulant activity, and a normal von Willebrand antigen level but decreased von Willebrand factor–ristocetin cofactor activity and collagen binding activity, as well as a decrease or absence of large von Willebrand factor multimers, simulating a type II von Willebrand disorder. The serum vitamin B_{12} level can be increased in 25% of cases.

In ET, BM karyotypes are characteristically normal. The absence of the Philadelphia chromosome and the *BCR-ABL* rearrangement excludes the diagnosis of CML. Studies to exclude CML as a cause of isolated thrombocytosis should be uniformly pursued in order to be certain that patients with CML presenting with isolated thrombocytosis are identified and receive appropriate therapy with tyrosine kinase inhibitors. Unfortunately, we have seen several such cases where CML was not excluded, which led to the implementation of inappropriate therapeutic strategies. Rare patients share two molecular markers of these two MPNs (*JAK2*V617F and *BCR-ABL*), but the CML phenotype predominates. Aneuploidy is seen in the minority of cases at diagnosis. In fact, ET is associated with a definite chromosomal abnormality in only 7.8% of cases, but with disease progression, there is an increased risk of aneuploidy. Specific chromosome abnormalities associated with ET have not been described, but abnormalities observed in PV and PMF, as well as in MDS, such as trisomy 1q, deletions of 5q, 13q, and 20q, trisomy 8, as well as monosomal karyotypes, have been reported. Many nonspecific chromosomal rearrangements have also been observed, such as a complex karyotype, the presence of a marker chromosome, and unusual translocations. More sensitive cytogenetic studies (see Chapter 57) in ET have not been performed extensively. In one reported study, the addition of fluorescence in situ hybridization increased detection of chromosomally abnormal clones by 15%. However, in 21 patients studied with oligoarray comparative genomic hybridization, one additional patient with deletion 13q was identified compared with conventional cytogenetics. Leukemic transformation of ET is characterized by the development of an abnormal karyotype in 60% to 100% of patients. Consistent chromosomal abnormalities associated with ET progression in *JAK2*V617F-positive patients are der(1)t(1;9) and der(1;7)(q10;p10). Of the eight reported ET patients with der(1;7), five received previous chemotherapy (chlorambucil, hydroxyurea,

TABLE 71.3 2016 Revised WHO Criteria for the Diagnosis of Essential Thrombocythemia, Pre-Fibrotic Form of PMF, and Overt PMF, and British Committee for Standards in Hematology Criteria for Diagnosis of Essential Thrombocythemia

WHO Essential Thrombocythemia Criteria

Major Criteria

1. Platelet count $\geq 450 \times 10^9$/L
2. BM biopsy showing proliferation mainly of the megakaryocyte lineage with increased numbers of enlarged, mature megakaryocytes with hyperlobulated nuclei. No significant increase or left shift in neutrophil granulopoiesis or erythropoiesis and very rarely minor (grade 1) increase in reticulin fibers
3. Not meeting WHO criteria for *BCR-ABL1*$^+$ CML, PV, PMF, myelodysplastic syndromes, or other myeloid neoplasms
4. Presence of *JAK2*, *CALR*, or *MPL* mutation

Minor Criteria

Presence of a clonal marker or absence of evidence for reactive thrombocytosis

Diagnosis of ET requires meeting all four major criteria, or the first three major criteria and the minor criterion

WHO Criteria for Pre-Fibrotic Form of PMF

Major Criteria

1. Megakaryocytic proliferation and atypia, without reticulin fibrosis >grade 1,[a] accompanied by increased age-adjusted BM cellularity, granulocytic proliferation, and often decreased erythropoiesis
2. Not meeting the WHO criteria for *BCR-ABL1*$^+$ CML, PV, ET, myelodysplastic syndromes, or other myeloid neoplasms
3. Presence of *JAK2*, *CALR*, or *MPL* mutation, or in the absence of these mutations, presence of another clonal marker,[b] or absence of minor reactive BM reticulin fibrosis[c]

Minor Criteria

Presence of at least one of the following, confirmed in two consecutive determinations:

a. Anemia not attributed to a comorbid condition
b. Leukocytosis $\geq 11 \times 10^9$/L.
c. Palpable splenomegaly
d. LDH increased to above upper normal limit of institutional reference range

Diagnosis of pre-PMF requires meeting all three major criteria, and at least one minor criterion

[a] See Table 71.8.

[b] In the absence of any of the three major clonal mutations, the search for the most frequent accompanying mutations (e.g., *ASXL1*, *EZH2*, *TET2*, *IDH1*/*IDH2*, *SRSF2*, *SF3B1*) is of help in determining the clonal nature of the disease.

[c] Minor (grade 1) reticulin fibrosis secondary to infection, autoimmune disorder or other chronic inflammatory conditions, hairy cell leukemia or other lymphoid neoplasm, metastatic malignancy, or toxic (chronic) myelopathies.

WHO Criteria for Overt PMF

Major Criteria

1. Presence of megakaryocytic proliferation and atypia, accompanied by either reticulin and/or collagen fibrosis grades 2 or 3[a]
2. Not meeting WHO criteria for ET, PV, *BCR-ABL1*$^+$ CML, myelodysplastic syndromes, or other myeloid neoplasms
3. Presence of *JAK2*, *CALR*, or *MPL* mutation or in the absence of these mutations, presence of another clonal marker,[b] or absence of reactive myelofibrosis[c]

Minor Criteria

Presence of at least one of the following, confirmed in two consecutive determinations:

a. Anemia not attributed to a comorbid condition
b. Leukocytosis $\geq 11 \times 10^9$/L
c. Palpable splenomegaly
d. LDH increased to above upper normal limit of institutional reference range
e. Leukoerythroblastosis

Diagnosis of overt PMF requires meeting all three major criteria, and at least one minor criterion

[a] See Table 69.8.

[b] In the absence of any of the three major clonal mutations, the search for the most frequent accompanying mutations (e.g., *ASXL1*, *EZH2*, *TET2*, *IDH1*/*IDH2*, *SRSF2*, and *SF3B1*) are of help in determining the clonal nature of the disease.

[c] BM fibrosis secondary to infection, autoimmune disorder, or other chronic inflammatory conditions, hairy cell leukemia or other lymphoid neoplasm, metastatic malignancy, or toxic (chronic) myelopathies.

British Committee for Standards in Hematology Criteria for Diagnosis of Essential Thrombocythemia

Requires A1–A3 or A1 + A3–A5:
A1: Sustained platelet count $>450 \times 10^9$/L
A2: Presence of an acquired pathogenic mutation (e.g., in *JAK2* or MPL)
A3: No other myeloid malignancy, especially PV, PMF, CML, or MDS
A4: No reactive cause for thrombocytosis and normal iron stores
A5: BM aspirate and trephine biopsy showing increased megakaryocyte numbers displaying a spectrum of morphology with predominant large megakaryocytes with hyperlobated nuclei and abundant cytoplasm

BM, Bone marrow; *CML*, chronic myeloid leukemia; *ET*, essential thrombocythemia; *JAK2*, Janus kinase 2; *MDS*, myelodysplastic syndrome; *MPL*, thrombopoietin receptor; *PMF*, primary myelofibrosis; *PV*, polycythemia vera; *WHO*, World Health Organization.

From Barbui T, Thiele J, Gisslinger H, et. al. The 2016 WHO classification and diagnostic criteria for myeloproliferative neoplasms: document summary and in-depth discussion. *Blood Cancer J*. 2018;8:15.

pipobroman, melphalan, cytosine arabinoside, anthracycline), and six transformed into acute leukemia. Although der(1)t(1;9) is a consistent nonrandom rearrangement associated with de novo PV and with PV progression, four ET patients had der(1)t(1;9) with different breakpoints (p13;p13) and (q10;p10). In ET, similar to PV, PMF, and other myeloid disorders, formation of trisomy 1q alone or subsequent formation of jumping +1q translocations should be considered as a clonal marker associated with disease progression or transformation to AML. As has been previously mentioned, approximately 50% of ET patients are *JAK2*V617F-positive, with only 4% having a high allele burden. Approximately 3% to 5% of patients have activating *MPL* mutations. Approximately 25% of patients harbor mutated *CALR* as either a type I (52-bp deletion) or type II (5-bp insertion).

Recent studies have indicated that there is cooperation between MPN driver gene mutations and other acquired somatic mutations within the hematopoietic clone. The effect of this cooperation on cellular phenotype is dependent on the type of nondriver mutation present. For instance, mutations in *TET2* or *DNMT3A* are associated with increasing dominance of the MPN clone and mutations in *ASXL1*, *IDH1/2*, *EZH2* or *TP53* are associated with transformation to MF or MPN-BP. The prevalence of mutations in *TET2* or *DNMT3A* is similar across all forms of MPNs (~12% in ET and 18% in PMF), whereas all other nondriver mutations have a higher prevalence in PMF than ET. For instance, splicing factor and epigenetic modifier mutations are present in more than 80% of PMF patients but less than 25% of ET patients. Approximately half of PMF cases have two or more mutations in nondriver genes. Therefore, the type and number of mutations in nondriver genes can be helpful in discriminating between ET and early forms of MF. It should also be noted that the sequence of acquisition of mutations can differ based on the driver mutation in ET. When the *CALR* mutation is the driver, this is almost always the initial mutation in the clone, whereas when *JAK2*V617F is the driver mutation, it can be the initial mutation or preceded by mutations in *DNMT3A*, *TET2*, and *ASXL1*.

TABLE 71.4 **Conditions Associated With Thrombocytosis**

Primary Thrombocytosis
Malignancies
Essential thrombocythemia
Polycythemia vera
Primary myelofibrosis
Chronic myeloid leukemia
Refractory anemia with ringed sideroblasts and thrombocytosis
Chronic myelomonocytic leukemia
MDS/MPN overlap
Familial thrombocythemia (inherited mutations in thrombopoietin or thrombopoietin receptor)
Secondary (Reactive) Thrombocytosis
Blood loss or iron deficiency
Infection
Inflammation
Disseminated malignancy
Hemolysis
Drug therapy
Hyposplenism
Cytokine administration
Spurious Thrombocytosis
Schistocytes
Cytoplasmic fragmentation of neoplastic cells
Cryoglobulinemia
Bacteria

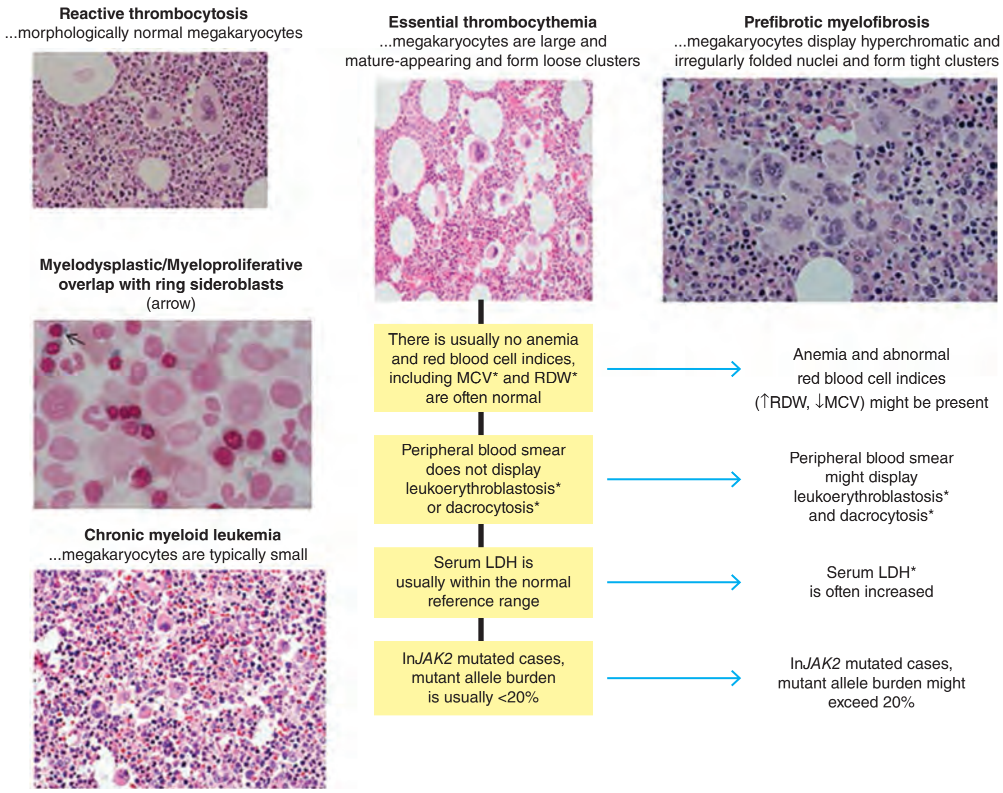
MDS, Myelodysplastic syndrome; *MPN*, myeloproliferative neoplasm.

DIFFERENTIAL DIAGNOSIS

There are numerous causes of primary, secondary, and spurious forms of thrombocytosis. A listing and description of the conditions that can lead to thrombocytosis are provided in Table 71.4 and Fig. 71.5. Primary thrombocytosis includes both acquired and hereditary forms. In acquired forms of primary thrombocytosis, the genetic abnormalities are present exclusively in hematopoietic cells, but in the hereditary forms, these underlying defects can be detected in both somatic and germline cells and are inherited. The discovery of *JAK2*, *MPL*, and *CALR* mutations has provided definitive diagnostic tools with which to diagnose the MPNs, including ET. These mutations, however, can be found only in approximately 75% of ET patients. Hence, it is reasonable to consider *JAK2*V617F analysis and search for a mutation in *CALR* or *MPL* when evaluating patients with otherwise unexplained thrombocytosis. A positive test result indicates an underlying MPN. However, further investigations, including a BM biopsy (see Table 71.3) as well as cytogenetic analyses, are still required to differentiate ET from the other chronic MPNs, as well as from MDS presenting with thrombocytosis, such as the 5q syndrome and refractory anemia with ring sideroblasts and thrombocytosis (RARS-T; see Table 71.3) and pre-PMF.

For those patients who present with thrombocytosis and who are triple negative for driver mutations, the first step in determining the cause of thrombocytosis is to exclude reactive forms of thrombocytosis. The causes of secondary or reactive forms of thrombocytosis are numerous, but the most common causes are infection, inflammation, hemolysis, severe exercise, malignancy, hyposplenism, and other causes of an acute-phase response (see Table 71.4). In a hospital population, patients with extreme thrombocytosis (>1000 × 10^9/L) are not particularly rare in adult or pediatric patient populations. Examination of the blood smear is important to avoid confusion with so-called *pseudothrombocytosis*. This occurs in a number of conditions in which platelet-sized particles of red or white blood cell fragments (CLL, TTP, hemoglobin H disease), schistocytes, microspherocytosis, and cryoglobulinemia are erroneously enumerated as platelets by automatic particle counters. Confirmation of increased numbers of platelets by examination of the peripheral smear will avoid misdiagnosis and unnecessary clinical evaluation.

Reactive thrombocytosis accounts for more than 88% to 97% of cases, whereas thrombocytosis caused by an MPN accounts for only a minority of cases. Reactive thrombocytosis is more common in all age groups except those in their eighth decade and older. Thrombotic and hemorrhagic events infrequently occur in patients with reactive thrombocytosis. These findings are in contrast to the enhanced risk of these two complications in patients with ET. This relatively high frequency of extreme thrombocytosis in an acute-care hospital emphasizes the need for caution in making a diagnosis of ET (Table 71.5). A number of groups have shown that reactive thrombocytosis may be a consequence of the elaboration of known cytokines in response to the underlying inflammatory or neoplastic disorder and is accompanied by an elevated erythrocyte sedimentation rate or a high C-reactive protein (CRP). Elevated levels of IL-1, IL-6, GM-CSF, G-CSF, and thrombopoietin have been detected in such patient populations and frequently in individuals with thrombocytosis caused by an underlying MPN. Elevation of thrombopoietin levels has not only been found in patients with reactive thrombocytosis but also in patients with ET. IL-6–induced thrombocytosis is mediated in part by secondary thrombopoietin production by the liver in inflammatory disorders and malignant diseases. CRP is an acute-phase reactant, the hepatic synthesis of which is mediated by IL-6. CRP levels are high in patients with high levels of IL-6. In one series, whereas 81% of patients with reactive thrombocytosis had elevated IL-6 or CRP levels, patients



Reactive thrombocytosis
...morphologically normal megakaryocytes
Essential thrombocythemia
...megakaryocytes are large and mature-appearing and form loose clusters
Prefibrotic myelofibrosis
...megakaryocytes display hyperchromatic and irregularly folded nuclei and form tight clusters
Myelodysplastic/Myeloproliferative overlap with ring sideroblasts (arrow)
Chronic myeloid leukemia
...megakaryocytes are typically small
There is usually no anemia and red blood cell indices, including MCV* and RDW* are often normal
Anemia and abnormal red blood cell indices (↑RDW, ↓MCV) might be present
Peripheral blood smear does not display leukoerythroblastosis* or dacrocytosis*
Peripheral blood smear might display leukoerythroblastosis* and dacrocytosis*
Serum LDH is usually within the normal reference range
Serum LDH* is often increased
InJAK2 mutated cases, mutant allele burden is usually <20%
InJAK2 mutated cases, mutant allele burden might exceed 20%

Figure 71.5 FEATURES TO DISTINGUISH BETWEEN DIFFERENT CAUSES OF THROMBOCYTOSIS. Laboratory and bone marrow characteristics of most common cause of thrombocytosis including reactive thrombocytosis, essential thrombocythemia, chronic myeloid leukemia, prefibrotic myelofibrosis and myelodysplastic/myeloproliferative overlap with ringed sideroblasts. **MCV*, mean corpuscular volume; *RDW*, red cell distribution width; *LDH*, lactate dehydrogenase; leukoerythroblastosis, presence of immature myeloid cells and nucleated red cells; dacrocytes, "teardrop" cells. *(From Tefferi A, Barbui T. with uncomplicated thrombocytosis secondary to an MPN had undetectable IL-6 levels. The mechanism by which IL-6 can stimulate thrombopoietin has recently been uncovered. In the liver, the Ashwell-Morell receptor (AMR) binds aging desialylated platelets, enabling their clearance but also activating transcription and translation of the thrombopoietin, facilitating platelet production (see Chapter 29). When IL-6 binds to its hepatic receptor (IL-6R), the signal transducing gp130 subunit is activated and this leads to STAT3 tyrosine phosphorylation and activation by gp130-associated JAK1.[13] There is evidence for cross talk between the AMR and the IL-6R to regulate TPO levels. TPO mRNA expression in hepatocytes is stimulated by IL-6. Loss of IL-6R, in animal models, results in increased expression of AMR, allowing for compensated TPO expression. Furthermore, IL-6R mRNA levels are increased in the liver of AMR knockout mice. After partial hepatectomy in mice, IL-6 played critical roles in hepatocyte proliferation and liver regeneration. Altogether, these studies indicate that both desialylated platelets and IL-6 lead to STAT3-mediated hepatic TPO mRNA expression downstream of the AMR-JAK2 and IL-6R-JAK1 signaling cascades, respectively. Interestingly, JAK1/2 inhibitors inhibit STAT3 activation and TPO mRNA production downstream of AMR binding, contributing potentially to the thrombocytopenia observed with the use of JAK inhibitors.[13] Low levels of both IL-6 and CRP are strongly indicative of the thrombocytosis being the consequence of an underlying MPN.

Both familial forms of thrombocytosis and the thrombocytosis that accompanies hematologic malignancies are examples of primary thrombocytosis. The MPNs are characterized by clonal hematopoiesis, but in the familial forms of thrombocytosis, hematopoiesis is polyclonal. Familial thrombocytosis is frequently inherited as an autosomal dominant disorder, and the affected individuals have elevated megakaryocyte and platelet numbers but normal WBCs and HCT levels. These familial forms of thrombocytosis are due to two types of germline mutations. Familial thrombocytosis, also known as hereditary thrombocytosis, exhibits autosomal dominant Mendelian transmission. It is characterized by the proliferation of megakaryocytes with overproduction of platelets in the absence of elevated hemoglobin and white blood cell count. In contrast to familial erythrocytosis, the OMIM database does not recognize different categories of familial thrombocytosis, considering all germline mutations under a single OMIM reference number (187950). There are two main causes of hereditary thrombocytosis, and they can arise from mutations involving either the thrombopoietin gene (THP) on chromosome 3, or more rarely, the thrombopoietin receptor gene (MPL) on chromosome 1.

Familial thrombocytosis, also known as hereditary thrombocytosis, exhibits autosomal dominant Mendelian transmission. It is characterized by the proliferation of megakaryocytes with overproduction of platelets in the absence of elevated hemoglobin and white blood cell count. The familial forms of thrombocytosis have been attributed in 20% of such families to two types of germline mutations. In the remaining families, the gene responsible for the thrombocytosis has yet to be identified.[14] An abnormality of thrombopoietin production or of the thrombopoietin receptor has been documented to be the basis of these inherited disorders leading to thrombocytosis. Because the median age of diagnosis of patients with these familial forms of thrombocytosis is 17 years, these disorders should be carefully considered in all *JAK2*V617F-, *MPLW*515L-, and *MPL*515K-, *CALR* mutation children with multiple family members with thrombocytosis.

Several different mutations have been reported in families in which excessive thrombocytosis has been attributed to increased thrombopoietin production.[15] A Dutch family with 11 family members and a Japanese family with eight family members were reported with a hereditary form of thrombocytosis that was inherited as an autosomal dominant. The thrombopoietin receptor in a Dutch family was normal, yet there was a G-to-C transversion in the splice donor site of intron 3 of the THP. All of the affected members of the Dutch family were shown to have elevated thrombopoietin levels. In this family, a point mutation in the THP was believed to lead to systemic overproduction of thrombopoietin, leading to a familial form of thrombocytosis. This was the first example of a human disease caused by increased efficiency of mRNA production. Actually, the translation of full-length thrombopoietin is almost completely inhibited by the presence in the 5′ untranslated region of seven AUG codons, which create seven upstream open reading frames (uORFs). These uORFs are potent inhibitors of translation, and mutations in this area cause thrombocytosis by eliminating the normal physiological inhibition of thrombopoietin mRNA translation. Additional families with thrombocytosis caused by a similar genetic mechanism have been identified.

Hereditary mutations of *MPL* can either result in loss of function and thrombocytopenia, or in gain of function and thrombocythemia, and are important models to analyze the mechanism of c-MPL activity. Familial thrombocytosis has been attributed to germline mutations of *MPL* (*MPL*-S505N, *MPL*-K39N, and *MPL*-P106L). *MPL*-S505N was first described in a Japanese pedigree of familial thrombocytosis that is inherited in an autosomal dominant fashion. This disorder has been attributed to a dominant-positive activating mutation of the cellular receptor of MPL. Eight additional Italian families with thrombocytosis and *MPL*-S505N have been identified. In these individuals, hematopoiesis is polyclonal. Etheridge et al.[16] described a novel, autosomal dominant germline mutation that causes familial ET resulting from a single-nucleotide substitution, generating the mutant kinase *JAK2*R564Q. Their data indicate that this mutation leads to isolated thrombocytosis. Mild thrombocytosis was observed as well as polyclonal hematopoiesis. Furthermore, increased activation of JAK2 was confirmed in the platelets of *JAK2*R564Q-positive family members compared with those without the mutation.

A polymorphism of the thrombopoietin receptor (MPL Baltimore, *MPL*-K39N) that is accompanied by thrombocytosis has also been described. This germline polymorphism is caused by a single-nucleotide substitution that results in a lysine-to-asparagine (K39N) substitution in the ligand-binding domain of MPL. The polymorphism occurs exclusively in African Americans and appears to have an autosomal dominant pattern of inheritance with incomplete penetrance because some heterozygotes have normal platelet counts while others have thrombocytosis. Approximately 7% of African Americans are heterozygous for *MPL*K39N. The mutation in the homozygous state is associated with extreme thrombocytosis with a reduced expression of platelet MPL, which has been proposed to affect the receptor's ability to bind thrombopoietin, resulting in its reduced clearance and increased stimulation of megakaryocytopoiesis. *MPL*-P106L is another germline mutation associated with thrombocytosis that has been found in 3.3% of Arabs. It leads to severe thrombocytosis in homozygotes and occasionally to mild thrombocytosis in heterozygotes. In the families described with this germline mutation, extreme thrombocytosis was associated with homozygosity and the mode of inheritance was regarded as being autosomal recessive with possible mild manifestations occurring in heterozygotes.

Subjects with familial forms of thrombocytosis are characteristically diagnosed at earlier ages than patients with ET. These disorders were initially considered to be associated with a benign clinical course, but follow-up of such families for longer periods of time has corrected this misperception. Overall, 23 members of a Dutch and a Polish family with a particular form of thrombocytosis attributed to excessive thrombopoietin production were shown to have similar thrombotic and hemorrhagic complications as individuals with ET. Also, these family members experienced vasomotor symptoms, including erythromelalgia and Raynaud phenomena, which responded to aspirin therapy but not hydroxyurea therapy. Furthermore, many of these patients developed splenomegaly as well as BM histopathologic findings that resemble an MPN, including BM hypercellularity, clustering of megakaryocytes, and a mild increase in BM fibrosis. Surprisingly, more prolonged follow-up of members of the Dutch family due to overproduction of thrombopoietin has revealed progression to symptomatic MF in one individual and progression to acute leukemia in a second family member. The patient with acute leukemia had not received any chemotherapeutic agents, and evaluation of the strength of the relationship between this high thrombopoietin condition and the development of acute leukemia requires further investigation of these families. Similarly, patients with an activating mutation of *MPL*, *MPL*-S505N, also have a high incidence of major thrombotic events, including stroke, myocardial infarction, and Budd-Chiari syndrome. In adult patients, overt BM reticulin and collagen fibrosis associated with mild reductions in hemoglobin levels have been observed, but differences in platelet counts, incidence of thrombotic episodes, or splenomegaly have not been observed when one compares these individuals with ET patients. In women with *MPL-S*505N, hematopoiesis was polyclonal, and the mutation was observed not only in hematopoietic tissues but also in other somatic tissues. Family members who are affected by this mutation appear to have a significantly shorter survival time than nonaffected family members who did not have thrombocytosis, with affected individuals dying most frequently of thrombotic events or complications of MF. By contrast, individuals with either *MPL*-K39N or *MPL*-P106L, which both involve the extracellular domain of MPL, affecting its ability to bind thrombopoietin, were not observed to have an increased risk for thrombosis, splenomegaly, or BM fibrosis.

Table 71.3 outlines the 2016 WHO criteria for the diagnosis of ET that incorporates *JAK2V7*617F, *CALR*, and *MPL* mutational analyses. RBC mass and plasma volume studies, if available, are sometimes helpful in differentiating between *JAK2*V617F-positive ET with borderline elevated hematocrits from patients with PV, but such patients likely represent a continuum of evolution of a *JAK2*V617F-positive hematologic malignancy. BM karyotypic analysis or studies of the *BCR-ABL* fusion gene are imperative in every patient to exclude the diagnosis of CML or to detect another clonal hematologic malignancy. This step is necessary because the natural history of these disorders is very different, and early therapeutic intervention with specific medical therapy for CML, such as a BCR-ABL tyrosine kinase inhibitor, is essential.

Occasionally, ET may be distinguished from refractory anemia with ringed sideroblasts associated with marked thrombocytosis (RARS-T), which is a myelodysplastic/MPN overlap syndrome (see Chapter 73). These patients present with thrombocytosis that is associated with moderate-to-severe anemia and frequently splenomegaly. Their BMs are characterized by the morphologic features of ET and the presence of more than 15% ringed sideroblasts. This entity likely represents a heterogeneous, poorly defined disorder that includes a spectrum of conditions sharing features of an MPN and a myelodysplastic disorder. RARS-T may develop from an *SF3B1*-mutated RARS through the acquisition of a *JAK2*, *MPL*, or *CALR* mutations in a subclone of hematopoietic cells. *SF3B1* is a gene encoding a core component of the RNA splicing machinery. This entity is associated with *JAK2*V617F in 58% of reported patients, *MPL*W515 mutation in 7% of reported patients, and *CALR* mutation in less than 5% of patients. Occasional patients with thrombocytosis and increased ringed sideroblasts but without anemia have also been described. Patients with RARS-T have a similar prognosis as ET patients. About 25% of patients with RARS-T have wild-type *SF3B1* and a subset of these have mutations in other splicing factor genes such as *U2AF1* and *SRSF2*.

Because patients with pre-MF frequently present with thrombocytosis, this form of PMF can frequently be difficult to distinguish from ET, and a recent study showed that 14% of patients diagnosed as ET prior to the revised 2016 WHO criteria defining pre-PMF were actually cases of pre-PMF. This early form of PMF was previously referred to as a *prefibrotic form of PMF*. In pre-PMF, nucleated RBCs, teardrop-shaped RBCs, immature myeloid cells, and megathrombocytes are observed in the peripheral blood. In the BM biopsy, the megakaryocytes are markedly abnormal, a morphologic finding that is helpful in distinguishing this entity from ET (see Fig. 71.5). In pre-PMF, the megakaryocytes often appear in clusters adjacent to the sinusoids; deviations in the nuclear cytoplasmic ratio in the megakaryocytes are observed with abnormal patterns of chromatin clumping; and plump clouds similar to a balloon-shaped lobulation of the nuclei are observed associated with minimal fibrosis or even absent reticulin fibrosis during this stage of PMF. The prevalence of each driver mutation was similar between pre-PMF and MF. However, certain nondriver gene mutations were more prevalent in overt PMF. The discrepancy between the prevalence of mutations in *ASXL1* (33.7% vs. 18%) and *EZH2* (12% vs. 3.6%) in overt versus pre-PMF, respectively, leads to more overt PMF patients meeting criteria to be high molecular risk (44.4% vs. 27.0%). Not all high-risk molecular mutations were discrepant between overt and pre-PMF as seen with *SRSF2* and *IDH1/2* mutations. Overt PMF was more likely to harbor ≥2 HMR mutations (13.6%) than pre-PMF (5.4%).[17] A recent study showed that increased plasma levels of dickkopf-related protein 1 (Dkk-1), an inhibitor of Wnt signaling, could differentiate different MPN subtypes, including discriminating between ET and pre-PMF.[18]

The presence of clonal hematopoiesis, at least in one lineage, quickly establishes the diagnosis of ET. Unfortunately, techniques to study clonality are currently not widely available and are restricted to the evaluation of female patients. Such studies may be particularly useful in young triple negative female patients with thrombocytosis. Probes for a variety of genes on the X chromosome can be informative for clonal analysis of blood cell production in more than 72% of female Americans. In such patients, the analysis of restriction fragment length polymorphisms can be used to establish a pattern of clonal hematopoiesis, which is indicative of a hematologic malignancy and established the diagnosis of ET in a young female patient with thrombocytosis who was lacking a driver mutation. Polyclonal hematopoiesis is found in all cases of reactive and familial thrombocytosis. Polyclonal hematopoiesis, however, does not exclude the diagnosis of ET because in several series, almost one-third of patients who met the clinical criteria for ET had polyclonal hematopoiesis in all studied lineages. The biogenesis of polyclonal ET has been described above.

At times, it is impossible to define the cause of an individual patient's thrombocytosis. In an asymptomatic patient, follow-up to determine whether the degree of thrombocytosis undergoes an increase is warranted. If additional clues to the cause of the thrombocytosis are subsequently revealed, a diagnosis will become apparent. Some reassurance is provided by reports of larger cohorts of patients, each with platelet counts of greater than 1000 × 10^9/L, which have been followed for years. Virtually none of the patients with reactive thrombocytosis demonstrated an increased risk of developing a cerebrovascular accident, thrombophlebitis, myocardial infarction, or a peripheral arterial thrombosis.

PROGNOSIS

The prognosis of ET patients is largely determined initially by their propensity during the early stages after diagnosis to develop thrombotic episodes and later to evolve to PV, MF, or eventually MPN-BP. Thrombotic events are largely the consequences of quantitative and qualitative abnormalities in blood cell numbers, while the evolution to MF and MPN-BP is now appreciated, partly due to the acquisition of additional myeloid gene mutations during the prolonged clinical course of ET patients that play a role in disease progression. Although the thrombotic risk of *JAK2*V617F+ ET patients is now appreciated to be greater than those with *CALR* mutations, Type 1 CALR-mutated patients appear to be at a higher risk of evolving to MF.[19] Significant efforts in the past have been spent trying to predict the outcomes solely based on clinical parameters. The probability that a patient with ET will survive 10 years ranges from 64% to 80%. In a large study from Spain with extensive follow-up, there was no substantial difference between the probability of survival of patients with ET and that of a control population. However, a study of 322 consecutive patients seen at the Mayo Clinic and followed for a median follow-up of 13.6 years showed a different pattern. The survival of patients with ET was similar to that of the control population during the first decade of disease, but it became significantly worse thereafter. Multivariable analysis identified an age at diagnosis of 60 years or older, leukocytosis (>15,000/µL), prior venous thrombosis, tobacco use, and diabetes mellitus as independent predictors of poor survival. The risk of developing leukemia or MF was low in the first 10 years (1.4% and 3.8%, respectively) but increased substantially in the second (8.1% and 19.9%, respectively) and third (24.0% and 28.9%, respectively) decades of the disease. The presence of the *JAK2*V617F mutation did not influence either survival or the rate of leukemic transformation in this analysis. The rate of leukemic transformation was higher in patients with platelet counts above 1000 × 10^9/L and abnormal hemoglobin levels. The development of MF was heralded by the appearance of immature myeloid precursors and dacryocytes in the blood smear and increased serum lactate dehydrogenase levels, followed by a reduction in platelet numbers and progressive splenomegaly. The presence of *CALR*, which occurs in 15% to 25% of patients with ET and is almost uniformly mutually exclusive with mutations in *JAK2* and *MPL*, is associated with younger age, male sex, higher platelet counts, lower hemoglobin levels, and a lower risk of thrombotic complications.

The International Prognostic Score for Essential Thrombocythemia (IPSET) was developed from the retrospective review of the clinical outcomes of 891 patients with ET diagnosed by WHO criteria in which age ≥60 years, leukocyte count ≥11 × 10^9/L, and history of thrombosis were determined to have a prognostic significance for survival, with weighted values of 2, 1, and 1 points, respectively.[9] The IPSET categories of low (no points), intermediate (1 to 2 points), or high (3 to 4 points) had corresponding median survivals of not yet reached, 24.5 years, and 13.8 years, respectively. Analysis of this cohort for thrombotic risk determined age greater than 60 years (1 point), history of thrombosis (2 points), presence of cardiovascular risk factors (1 point; diabetes, hypertension, smoking) and the presence of mutated *JAK2* (2 points) as independent risk factors. Low-risk (0 to 1 points), intermediate-risk (2 points), and high-risk (3+) categories were associated with 1.03%, 2.35%, and 3.56%/year risk of thrombosis, respectively.[20]

The IPSET-thrombosis score was revised by reanalysis of the original IPSET-thrombosis data in 1019 ET patients for whom *JAK2*V617F mutational status was known. This study is of importance since it was the initial attempt to include mutational status into prognostic scoring systems. The aim of this reanalysis was to define the impact of the *JAK2* mutation and cardiovascular risk factors on thrombosis-free survival in ET patients.[11] The presence of *JAK2*V617F clearly impacted the risk of thrombosis. Cardiovascular risk factors did not further worsen the risk of thrombosis in patients who had a history of thrombosis. Results from this analysis led to a four-tier risk stratification based on three adverse features: age greater than 60, thrombosis history, and *JAK2V617F*. Risk categories include very low (no adverse variables), low (presence of *JAK2V617F* alone), intermediate (age >60 years) and high (thrombosis history or age >60 years with *JAK2V617F*). Although this revised prognostic scoring system was validated in 585 ET patients, it will require validation using prognostic studies before it is universally implemented.[19]

Paz and coworkers initially recognized that the prognosis of ET patients is due to two major complications: thrombosis in the time period prior to, or in, the short term following diagnosis; and the evolution to MF and MPN-BP during the long term follow-up of ET patients. Grinfield et al.[2] utilized this concept to develop a genomic classification of MPNs. They performed whole-genome sequencing of 2035 MPN patients, of whom 1321 had ET and had participated in the ET trials conducted by this group. Using this approach, they were able to identify eight genomic subgroups of MPN patients to predict which patients were at the highest risk of progressing to MF or MPN-BP.[2] They concluded that death in the early phases of ET was primarily influenced by age, not genomic factors. However, genomic features were found to be predictive of the progression of ET or preMF to MF or more overt forms of MF. The efforts of Grinfeld and coworkers are important in understanding ET disease progression, but unfortunately, at present, it does not affect treatment options due to the lack of therapeutic options that specifically target these genomic changes.

Recently, work by Tefferi et al. determined that certain non-driver mutations influenced survival in ET patients. Next-generation sequencing results of 502 ET patients were analyzed and splicesosome mutations in *SF3B1* and *SRSF2* predicted inferior overall survival, while mutations in *SF3B1* and *U2AF1* predicted inferior MF-free survival. *TP53* mutations were associated with transformation to MPN-BP. This enabled the development of a mutation-enhanced prognostic model for ET that incorporates the presence of adverse mutations (*SRSF2*, *SF3B1*, *U2AF1*, and *TP53*) (2 points) with high-risk clinical parameters: age greater than 60 years (4 points), male sex (1 point), and leukocyte count $\geq 11 \times 10^9$/L (1 point). Based on data from 451 ET patients merged from the Mayo Clinic and University of Florence, the three-tiered modified MIPSS for ET categories of low-risk (0 to 1 points), intermediate-risk (2 to 5 points) and high-risk ($\geq$ 6 points) corresponded to median survivals of 34.4 years, 14.1 years, and 7.9 years, respectively. Mutational-based prognostic scoring of ET patients will need to be further validated in larger cohorts.

A major determinant of the prognosis of a patient with a presumptive diagnosis of ET depends on the discrimination of whether such patients actually have true ET or an early form of MF, based on histopathologic and clinical criteria adopted by the WHO (see Table 71.3).[14] In a group of 891 patients with a prior diagnosis of ET with BM biopsies evaluated retrospectively, 16% were reclassified as having pre-PMF through histopathology. Thrombosis rates and *JAK2*V617F positivity were similar in the two groups. However, patients with pre-PMF had higher leukocyte counts, lower hemoglobin levels, higher platelet counts, higher lactic dehydrogenase levels, greater numbers of circulating CD34$^+$ cells, and a greater incidence of palpable splenomegaly than patients with true ET. Survival was reported to be significantly inferior for those patients with pre-PMF compared with patients with histopathologically validated ET (Fig. 71.6). In one series with a median follow-up of approximately 7 years, the median survival of patients with ET ranged from 16 to 21 years, and the survival of patients with pre-MF ranged from 10.8 to 14.4 years, with the incidence of thrombosis being similar and the majority of deaths being attributed to progression to overt PMF and acute leukemia. Although the patients with ET enjoyed a more favorable outcome, the 15-year cumulative incidences of overt MF and acute leukemia were still 9.3% and 2.1%, respectively, emphasizing the seriousness of this diagnosis, especially in younger patients.[21]

Death of ET patients predominantly results from thrombotic complications, but transformation to MPN-BP is an important cause of mortality. The phenotype of the blast cell can be myeloid, myelomonocytic, megakaryocytic, of mixed lineage, or even lymphoblastic. According to the data mentioned earlier, the risk of patients with ET transforming into acute MPN-BP is greater than that of normal individuals. This is a phenomenon shared with the other MPNs. The risk of developing MPN-BP after treatment with hydroxyurea alone has been reported to increase only slightly (3% to 4%), but the sequential use of hydroxyurea with other cytotoxic agents, such as busulfan or pipobroman, significantly increases the risk of developing a secondary leukemia.

The development of MPN-BP is associated with a deletion of the short arm of chromosome 17, trisomy of the long arm of chromosome 1, and monosomy 7q. The 17p loss is associated with the loss of TP53. ET patients with such abnormalities of TP53 have been shown by Grinfeld and coworkers to have an inferior outcome due to disease progression.[2] 17p loss has been attributed to hydroxyurea treatment by some but not all investigators. The median survival after the development of myelodysplasia or MPN-BP is 4 months. MPN-BP, which develops following ET, is frequently refractory to standard induction chemotherapy but has been recently reported to be responsive to hypomethylating agents, including 5-azacytidine and decitabine. Because allogeneic stem cell transplantation can be curative, rapid referral to a transplant center is suggested if the patient has an appropriate performance status and an allogeneic stem cell donor is available.

THERAPY

At present, the goal of treating patients with ET is to prevent additional thrombotic and hemorrhagic events[20] without increasing

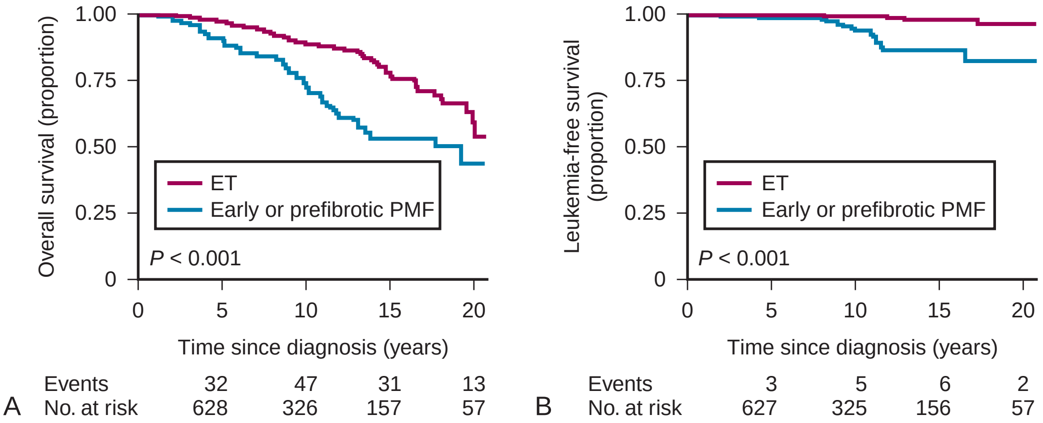

Figure 71.6 Overall (A) and leukemia-free (B) survival of patients with true essential thrombocythemia (ET) versus early or prefibrotic primary myelofibrosis (PMF). *(Data from Barbui T, Thiele J, Passamonti F, et al. Survival and disease progression in essential thrombocythemia are significantly influenced by accurate morphologic diagnosis: an international study. J Clin Oncol. 2011;29:3179.)*

TABLE 71.6 Risk Factors for Thrombosis in 100 Patients With Essential Thrombocythemia

Risk Factor	Incidence of Thrombosis (% Patient-Year)	Relative Risk (95% CI)	*P*
Age (Years)			
<40	1.7	1.0[a]	
40–60	6.3	3.9 (0.7–21.5)	NS
>60	15.1	10.3 (2.1–51.5)	< 0.001
Previous Thrombosis			
No	3.4	1.0[a]	< 0.0005
Yes	31.4	13.0 (4.1–1.5)	

[a] Reference category.

the risk of transformation to post-ET MF, MDS, or MPN-BP. Age (>60 years of age), the presence of *JAK2*V617F, and the history of a prior thrombosis are widely accepted predictors of a patient developing additional thrombotic events during follow-up (Table 71.6). Other predictors of cardiovascular morbidity include a history of smoking, hypertension, obesity, diabetes mellitus, and congestive heart failure, and a white blood cell count greater than 11 × 10^9/L. Ironically, patients with platelet counts greater than 1000 × 10^9/L have a lower risk of developing arterial thrombosis and a higher risk of bleeding. These parameters have been widely used by clinicians to stratify ET patients according to their risk of developing additional thrombotic events but are not known to delay disease progression. Such stratification strategies have been used to make treatment decisions to reduce the platelet count. It is important to emphasize that such risk factors have been identified based on retrospective analyses of registries of ET patients that have largely not been created using modern molecular and histopathologic diagnostic tools and are not known to alter the risk of a patient progressing to MF or MPN-BP. Using such patient-stratification strategies, patients have been placed into high-, intermediate-, or low-risk or very low-risk groups based on their predicted risk of developing an additional life-threatening thrombotic event. This strategy is uniformly implemented throughout Europe and North America. The benefit of this strategy is based on a single clinical trial that indicated that the reduction of platelet numbers to less than 600 × 10^9/L with hydroxyurea therapy was associated with a reduction in the development additional thrombotic events compared with a control group (see Fig. 71.2). This study involved a total of 114 patients, and the median follow-up period was only 27 months. Greater degrees of platelet suppression have not been shown to be associated with a further reduction in the possibility of developing a thrombotic episode, which in hydroxyurea-treated high-risk patients has been reported to be 1.66% per year.

Although the implementation of such a strategy is widely accepted, it is important to be aware that this approach is not based on robust data that one associates with modern-day evidence-based medicine. In fact, in several studies, an elevated leukocyte count of above 11 × 10^9/L has been more closely associated with the risk of developing additional thromboses than the degree of elevation of the platelet count, and a recent prospective study of 261 patients for the anagrelide registry confirmed that increased leukocyte count not only increases the risk of major thrombosis but also decreases the time to such an event.[22] The effects of leukocytosis on thrombotic risk remains, however, controversial. Carobbio and coworkers, however, by performing a systematic literature review and meta-analysis of greater than 30,000 patients with ET or PV, found that the greatest effect of leukocytosis on thrombotic risk was in ET, rather than PV, and that this effect was exclusively related to arterial events and not venous events. This study has important limitations since a consensus definition of leukocytosis to optimally predict the risk of developing vascular events could not be identified.[23] These conflicting reports in the literature among experts in this field make it increasingly difficult to be dogmatic about who to treat with platelet-lowering agents and what the target platelet count should be. The risk stratification of patients should not be ignored, and patients with life-threatening thrombosis or disabling symptoms because of microcirculatory problems should receive drugs that lower the platelet count. If a patient of any age has excessive thrombocytosis and a thrombotic or hemorrhagic event, that patient must be treated with platelet lowering agents. However, for asymptomatic ET patients in so-called *high-risk categories based on age alone*, the decision to embark upon a strategy including platelet-lowering agents remains murky and is more based on personal treatment decisions rather than volumes of data. The treatment of asymptomatic low-risk patients with ET remains largely problematic, yet greater insight into the management of such patients has recently been gained.

Management of ET patients with life-threatening hemorrhagic or thrombotic episodes is more straightforward. Life-threatening thrombotic events in patients with extreme thrombocytosis rarely require plateletpheresis, but when implemented, it should be combined with the institution of myelosuppressive therapy. To place this practice in perspective, over the last 14 years at our institution, we have not used this approach on a single patient. Plateletpheresis should not be used in patients undergoing major bleeding events due to its ability to lead to hemodynamic instability or in patients with thrombotic events with modest or moderate thrombocytosis. In an ET patient with an active thrombosis and extreme thrombocytosis, immediate physical removal of large numbers of platelets is an option because chemotherapeutic agents generally require several weeks before platelet counts can be reduced to normal levels. It is recommended to reduce the platelet count to below 600,000/mm^3 by each plateletpheresis and it is suggested that achievement of such a goal requires the passage of two blood volumes over a 3 to 4-hour period. Long-term plateletpheresis is an ineffective means of controlling thrombocytosis, presumably because of the rapid rate of production of platelets. Therefore most clinicians begin by administering a chemotherapeutic agent that has a rapid onset of action, such as hydroxyurea at doses of 2 to 4 g/day, simultaneously with the institution of platelet-pheresis. The dose of hydroxyurea requires close monitoring with an appropriate reduction of dose to avoid excessive myelosuppression. At present, we avoid plateletpheresis in ET patients with acute thrombosis but rather choose to institute hydroxyurea and anticoagulation immediately. Plateletpheresis is not recommended for asymptomatic patients with extreme thrombocytosis such as a platelet count greater than 2000 × 10^9/L in spite of the anxiety that such numbers might create in the treating physician.

In patients found to have ET and a current or past history of a thrombotic event, little controversy exists as to the need for lowering platelet numbers. The large number of thrombotic complications that occur in patients with ET who smoke points to the urgent need for smoking cessation. Most investigators try to normalize the platelet count or reach a platelet count at which the symptoms of the high-risk patient resolve. Although major bleeding episodes requiring hospitalization are rare, patients with extreme thrombocytosis (>1500 × 10^9/L), acquired von Willebrand syndrome, and a history of a hemorrhagic episode are clearly at the risk of developing additional bleeding complications. These patients require reduction of the increased platelet numbers to the normal range with the use of a variety of agents, including hydroxyurea, anagrelide, or IFN-α.

Another situation that requires treatment is discomfort caused by erythromelalgia, or the progression of erythromelalgia, to frank gangrene. Erythromelalgia patients respond within days to low-dose aspirin therapy or platelet-reduction therapy. Patients with frank gangrene require sustained normalization of platelet numbers with myelosuppressive therapy and aspirin with the goal of preserving digits or limbs that remain in danger.

During the 1980s and 1990s, hydroxyurea became the drug of choice for the treatment of ET. The impetus for this practice was based on the knowledge that agents such as ^{32}P and alkylating agents such as melphalan and busulfan were leukemogenic. The popularity of the ribonucleoside reductase inhibitor, hydroxyurea, for the management of ET was due to the belief in the early 1970s that it was nonleukemogenic. Hydroxyurea can be administered at a dose of 15 mg/kg initially, with an adjustment of the dose to maintain a platelet count (at the least) below $600 \times 10^9/L$ without inducing significant neutropenia. Evidence to target lower platelet counts to further reduce the risk of additional thrombotic events is not available. After the agent is started, frequent monitoring of blood counts is mandatory to avoid the development of neutropenia or thrombocytopenia until the maintenance dose is determined. The use of this drug in a high-risk group of patients with a reduction of platelet numbers to less than $600 \times 10^9/L$ has resulted in a reduction of thrombotic events compared with a control population. In addition, hydroxyurea is capable of normalizing the WBC, which is thought by many to be of potential importance since elevated WBCs are thought to contribute to the increased thrombotic risk in ET patients. The reduction of platelet numbers to normal levels reduces but does not entirely eliminate the occurrence of additional thrombotic episodes.

The role of hydroxyurea plus aspirin versus aspirin alone was analyzed in a randomized clinical trial of " intermediate-risk" ET patients who were 40 to 59 years old and lacked high-risk features including a history of thrombosis, ischemia, embolism, hemorrhage, extreme thrombocytosis (platelet count $\geq 1500 \times 10^9/L$), hypertension, or diabetes. These investigators classified ET patients of ages from 40 to 59 years into the intermediate-risk group since they had previously shown that this patient population has a higher thrombotic risk than younger patients. Most investigators in this field would have classified such patients as being low-risk. The addition of hydroxyurea to aspirin therapy did not reduce vascular complications of ET or myelofibrotic/leukemia transformation, confirming that low-risk patients should not receive cytoreductive therapy.[24] This report provides evidence for the lack of benefit of myelosuppressive therapy in low-/intermediate-risk ET patients. This type of therapy should be reserved exclusively for patients with a history of a thrombotic or bleeding event. This report should dissuade clinicians from reflexively treating the platelet count irrespective of the degree of thrombocytosis. Such defensive approaches to treating ET patients are discouraged.

Hydroxyurea use is associated with some toxicity, including dose-related neutropenia, fever, nausea, stomatitis, hair loss, azoospermia, infertility, nail discoloration, and lower extremity and oral ulcerations, as well as an increased risk of developing squamous cell carcinoma of the skin. Many of these problems resolve with the withdrawal of the drug or dose reduction, but leg ulcers can be persistent, sometimes requiring skin grafting. These ulcers typically heal within 1 to 9 months of the cessation of therapy. Such leg ulcers have been reported to occur in 9% of the patients treated with hydroxyurea and are an indication for the immediate discontinuation of therapy and elimination of any rechallenge with the drug. Hydroxyurea is also not universally successful in controlling thrombocytosis; resistance to hydroxyurea has been reported in 11% to 17% of cases. The criteria for defining resistance or intolerance to hydroxyurea have been established by an International Working Group. They include a platelet count greater than $600 \times 10^9/L$ after 3 months of at least 2 g/day of hydroxyurea (2.5 g/day in patients with a body weight >80 kg); a WBC less than $2500/mm^3$ or hemoglobin less than 10 g/dL at any dose of hydroxyurea; presence of leg ulcers or other unacceptable mucocutaneous manifestations at any dose of hydroxyurea; and hydroxyurea-related fever. In such situations, hydroxyurea can be substituted for (or combined with) other platelet-lowering agents. These criteria for hydroxyurea resistance are imperfect because they do not include the development of a thrombotic event while on therapy, which is the central goal of therapy. Whether such patients who develop a new thrombosis would benefit from the continued use of hydroxyurea or use of another therapeutic agent has not been explored.

The risk of evolving to acute leukemia is extremely low in untreated ET patients. More recent prospective studies, both in ET and PV, have confirmed that hydroxyurea therapy is associated with a low incidence of leukemic transformation when used alone (<5%) and with long-term follow-up (≤14 years). However, the leukemic risk increased significantly when the drug was used before or after treatment with alkylating agents, particularly busulfan. One can conclude from these studies that hydroxyurea therapy alone is less leukemogenic than alkylating agents or ^{32}P alone, but a small increased risk of the development of leukemia secondary to its use cannot be completely excluded. Of concern is the observation that a high proportion of AML and MDS occurring in ET patients treated with hydroxyurea alone have morphologic, cytogenetic, and molecular characteristics of the 17p deletion syndrome that is associated with the deletion of TP53. These patients are reported to have a typical form of dysgranulopoiesis characterized by hypolobulated polymorphonuclear leukocytes with small vacuoles in neutrophils and *TP53* mutations. By contrast, Kubesova and coworkers reported that in MPN patients, age was the strongest factor affecting the incidence of low VAF *TP53* mutations and that they could not document a significant age-independent association between the *TP53* mutations and the administration of hydroxyurea. The phobia concerning the use of hydroxyurea in ET patients articulated by some is clearly excessive. A more practical approach would be to avoid its use in younger patients who are in their reproductive years, and due to its ease of administration, to use this agent in older high-risk patients as the standard of care. It should be emphasized that the effects of hydroxyurea are frequently quickly reversible and therapy should be continued as long as the patient has thrombocytosis. Ironically, if ET patients have progressive reductions in platelet numbers into the normal range, allowing hydroxyurea therapy to be discontinued, that scenario should raise the possibility of progression to MF.

When considering the risk-to-benefit ratio, one can conclude that hydroxyurea therapy is the first-line therapy for ET patients with a high-risk of developing an additional thrombosis, including those older than 60 years of age or with a history of a thrombotic episode. As previously suggested, such nonleukemogenic drugs as IFN-α, anagrelide, or pegylated IFN are preferred in patients younger than 40 years of age who have experienced a major thrombotic or bleeding event. An alternative to hydroxyurea is therapy with anagrelide. Data on the use of anagrelide in ET suggests that it is nonleukemogenic. Anagrelide is a member of the imidazo(2,1-b)quinazolin-2-1 series of compounds. When studied in humans, it was noted that anagrelide, in small doses, produced thrombocytopenia. The drug acts primarily by reducing the megakaryocyte size and ploidy. It also decreases megakaryocyte proliferation. Anagrelide therefore appears to lower platelet counts, primarily by interfering with the development of megakaryocytes. Anagrelide suppresses megakaryocytopoiesis by selectively reducing the expression levels of GATA-1, FLI-1, NFE-2, and FOG-1 in cells belonging to the megakaryocytic lineage. The effects of anagrelide do not involve thrombopoietin-mediated signal transduction events. GATA-1 and FOG-1 play critical roles in megakaryocytic differentiation. Anagrelide in low doses is effective in lowering the platelet count in 93% of patients. Most importantly, it is effective despite resistance to prior therapies. Resistance to anagrelide therapy has not been documented, but occasionally patients have been observed to require extraordinarily high doses to control excessive thrombocytosis. The recommended initial dose is 0.5 mg orally, two to four times a day. The dose should be increased by 0.5 mg/week to control thrombocythemia. The dose of anagrelide should not exceed 10 mg/day or a 2-mg/dose. Excessive use will result in predictable thrombocytopenia and increase the likelihood of side effects. The median maintenance dose in patients with ET is 2 mg/day administered in divided doses. Data on more than 3000 patients with a variety of MPNs complicated by extreme thrombocytosis are available. In addition, follow-up of more than 500 patients for more than 5 years has been reported. Anagrelide has been shown to be an effective drug in the treatment of ET, resulting in a median time to response of 2.5 to 4 weeks. An effect on platelet numbers is usually noted within 6 to 10 days. Anagrelide leads to a reduction in hematocrit in 25% to 36% of patients, but it has no effect on white blood cell numbers, systemic symptoms, or the degree of splenomegaly. Buxhofer-Ausch and co-workers using a registry of 309 ET patients with normal WBC numbers have reported the effectiveness of lowering the platelet count with anagrelide below 600×10^9/L on the risk of developing a major thrombotic event in ET patients.

The most common side effects of anagrelide result from its vasodilatory and positive inotropic actions. These effects resulted in complaints of headache, dizziness, fluid retention, palpitations, and high-output cardiac failure. The vasodilatory effect leads to reduced renal blood flow, resulting in fluid retention. In addition, gastrointestinal complications, such as nausea, abdominal pain, and diarrhea, are prominent. These side effects usually develop within 2 weeks of initiation of therapy and frequently diminish in severity or resolve within 2 weeks of continued therapy. Because of its ability to promote fluid retention and the development of tachyarrhythmias, anagrelide therapy should be used with caution in patients with cardiac disease and should be administered carefully to elderly patients. If congestive heart failure or arrhythmias other than tachycardia develop, anagrelide therapy should be discontinued. Prolonged anagrelide therapy may be associated with a potentially irreversible drug-induced cardiomyopathy that is reminiscent of tachycardia-induced cardiomyopathy. Dose reduction can be used to lessen the degree of tachycardia or fluid retention. Before the institution of anagrelide, a basic cardiac evaluation should be performed, including an assessment of cardiac risk factors, a careful cardiac history, and an electrocardiogram, which can be used as a baseline if the patient develops rhythm disturbances. Although most adverse effects are mild or moderate, in one series, therapy was discontinued in 16% of patients because of intolerable side effects, especially headache, nausea, fluid retention, and, rarely, frank congestive heart failure. Anagrelide has no mutagenic activity, but its use is not currently advised during pregnancy. Because of its small molecular weight, it is believed to be capable of crossing the placenta and thus may lead to fetal thrombocytopenia. Anagrelide appears to be a suitable drug for the treatment of young, symptomatic patients with ET and for those who are resistant or refractory to front-line treatment with hydroxyurea.

Hydroxyurea and anagrelide have been compared in a large, randomized trial of 809 “high-risk” patients with ET in combination with low-dose aspirin (75 to 100 mg/day). The dose of each cytoreductive agent was titrated to achieve a platelet count less than 400×10^9/L and long-term control was attained in each treatment arm. Overall, patients randomized to anagrelide (and aspirin) were more likely to reach the composite primary endpoint of major thrombosis (arterial or venous), major hemorrhage, or death from vascular causes ($P = 0.03$; Fig. 71.7). When individual endpoints were assessed, arterial thrombosis, major hemorrhage, and the development of MF were all significantly more frequent in patients treated with anagrelide (7% vs. 2%; P = 0.004, 0.008, and 0.01, respectively). Anagrelide and aspirin seemed to offer at least partial protection from thrombosis because the prevalence of thrombotic events (8% at 2 years) was significantly less than that observed in the control arm of a previous study (28%). Intriguingly, the number of venous thromboses was less frequent in patients treated with anagrelide ($P = 0.006$). In addition, patients with *JAK2*V617F-positive ET were more sensitive to therapy with hydroxyurea but not anagrelide. Recent analyses of anagrelide-treated ET patients indicate responsiveness irrespective of the driver mutation status. In long-term follow-up of 67 patients with ET treated with anagrelide, therapy-related anemia was more frequent in *CALR*-mutated patients without differences in thrombotic rates among the four molecular subtypes. Also, the incidence of discontinuation of anagrelide therapy because of drug-related adverse events was significantly greater than that observed with patients receiving hydroxyurea. Based on this large randomized remarkable study, hydroxyurea is presently considered first-line therapy for patients with high-risk ET (Table 71.7). Although equivalent control of the platelet count was achieved with both agents, hydroxyurea proved superior, perhaps because of its ability to reduce not only platelet numbers but also leukocyte numbers, which have been associated with arterial thrombosis in ET patients. In addition, the combination of anagrelide and low-dose aspirin was associated with a higher incidence of bleeding episodes, suggesting that aspirin therapy might be best avoided in patients being treated with anagrelide.

		Hydroxyurea
50–75	Hydroxyurea	Interferon
		Anagrelide
>75	Hydroxyurea	Anagrelide
		Busulfan

The ANAHYDRET study was a prospective, randomized, noninferiority study comparing hydroxyurea to anagrelide treatment in 259 patients with treatment-naïve, high-risk ET (WHO diagnosis confirmed). Anagrelide was determined to be noninferior to hydroxyurea based on equivalent rates of thrombotic (arterial and venous) and hemorrhagic (major and minor) complications. A criticism of this study was the low rate of aspirin use in this study, which was approximately 28% in both arms, and the lack of data indicating relative rates of transformation to MF.

Analysis of 3649 high-risk ET patients undergoing cytoreductive treatment as participants of a phase IV Evaluation of Anagrelide Efficacy and Long-term Safety revealed fewer thrombotic events in patients treated with anagrelide. However, a greater degree of hemorrhage and transformation to MF in patients treated with anagrelide. Patients who received cytoreductive therapies other than anagrelide had a greater risk of leukemic transformation and the development of other malignancies.

Interestingly, Alvarez-Larrán et al., while reporting the results of myelosuppressive therapy from the Spanish Registry of ET, indicated that *CALR*-mutated ET is less responsive to such a therapeutic approach. About 1104 ET patients were in the study and either received cytoreductive treatment with hydroxyurea ($n = 977$), anagrelide ($n = 113$), or other agents ($n = 14$). Hydroxyurea and anagrelide were similarly effective in *CALR*-mutated ET patients. At 12 months, rates of complete hematological response were 40% in *CALR*-mutated cases and 67% of *JAK2*V617F+ cases. Median time to complete hematological remissions was longest in the *CALR*-mutated cases (705 days) compared to cases with other driver mutations (192 days for *JAK2*V617F, 433 for *MPL*-mutated) and cases that were triple negative (343 days) ($P < 0.0001$). Complete remission duration was shortest in *CALR*-mutated ET. Resistance/intolerance to hydroxyurea occurred more frequently in *CALR*- mutated patients (23%) and *MPL*-mutated patients (27%) than in *JAK2*V617F+ (5%) and triple negative cases (15%) ($P < 0.0001$). This report is of importance since it indicates for the first time that *CALR*-mutated ET is less sensitive to conventional myelosuppressive agents, suggesting that new therapeutics are needed for this genotype. This report has limitations since it did not evaluate the effects of such interventions on the incidence of thrombotic events. Since *CALR*-mutated patients have higher platelet numbers, lower WBCs, and a lower risk for thrombotic events, the application of lessons learned from treating a group of ET patients irrespective of genotype might not be appropriate. The Spanish group also suggested that platelets to be targeted with myelosuppressive therapies might be different for patients with other mutations. Such a personalized approach to myelosuppressive therapy in high-risk ET patients is worthy of further evaluation in a prospective study.

IFN-α has been used to treat MPN-associated thrombocytosis since the 1990s. IFN-α likely acts by promoting cycling of MPN hematopoietic stem cells, activating the TP53 pathway, directly inhibiting megakaryocyte colony formation and secondarily by inhibiting the expression of thrombopoietic-stimulating cytokines, such as GM-CSF, G-CSF, IL-3, and IL-11, and by stimulating the production of negative regulators of megakaryocytopoiesis, such as IL-1ra (receptor agonist) and macrophage inflammatory protein 1 (MIP-1a). IFN-α inhibits thrombopoiesis by suppressing thrombopoietin-induced phosphorylation of the JAK2 substrates, MPL and STAT5. Furthermore, IFN-α also induces the production of suppressor of cytokine signalling-1, which inhibits thrombopoietin-mediated cell proliferation. In a total of 212 patients treated with IFN-α in a total of 11 different clinical trials, a response rate of approximately 90% has been reported. Therapy was administered to outpatients, most frequently at an initial dose of 3 million units daily, and usually produced a rapid decrease in platelets within 2 months. The mean time to complete response with a daily dose of 3 million units was about 3 months. IFN-α was effective in patients who had received other chemotherapeutic agents and in patients resistant to conventional cytotoxic drugs. In the majority of patients, the IFN dose required to maintain a normal platelet count during maintenance therapy was lower than the induction dose. In one study, 61% of patients required 3 million units three times a week, 15% once a week, and 24% daily. In addition, sustained remissions that persisted for 3 to 36 months were achieved with IFN-α therapy in 9% to 16% of patients. IFN-α is reported to be nonmutagenic and does not cross the placenta, making it a useful drug for the treatment of symptomatic pregnant patients with ET. Toxicity, especially in older patients, the need for parenteral administration, and cost limit the usefulness of IFN-α. Side effects include flu-like symptoms during induction therapy, such as fever, bone and muscle pain, fatigue, lethargy, and depression. Symptoms are frequently controlled with acetaminophen. Long-term administration of IFN-α can result in mild weight loss; alopecia; retinal abnormalities; and rarely, a reversible form of sarcoidosis and a reversible form of left-sided heart failure; and the development of autoimmune conditions, including thyroiditis leading to hypothyroidism and autoimmune hemolytic anemia. Patients may develop neutralizing antibodies to recombinant IFN, leading to a concomitant rise in platelet numbers. Approximately 25% of IFN therapy-treated ET patients discontinued therapy due to poor compliance or limiting side effects.

A semisynthetic protein-polymer conjugate of IFN-α2b, pegylated IFN (peg-IFN-α2b), was anticipated to be superior to unmodified IFN as related to its adverse event profile and efficacy when used to treat ET patients. This formulation of IFN provides prolonged activity that permits once-weekly dosing. Normalization of blood counts occurred after a median time of 2 to 3 months; 12% of patients discontinued therapy because of inability to tolerate the drug, and 17% did not achieve normalization of their platelet counts. The majority of side effects were WHO grade 1 or 2, although some encountered grade 3 toxicity, primarily fatigue and flu-like symptoms. More importantly, no thromboembolic or hemorrhagic complications occurred during the period of treatment, although 12 thrombotic events occurred in 42 patients (24%) in the 24 months before the institution of therapy. This form of IFN, however, appears to lead to a similar frequency and severity of side effects during long-term use as experienced with conventional IFN.

Interestingly, the use of another pegylated form of IFN (peg-IFN-α2a) in patients with PV was able to decrease the percentage of mutated *JAK2* allele in 24 out of 27 treated patients, from a mean of 49% to a mean of 27%. The use of this form of IFN appeared to be associated with fewer side effects than standard forms of IFN or peg-IFN-α2b. This form of pegylated IFN has been used to treat approximately 40 patients with ET, with more than 75% of patients achieving a complete hematologic remission. Almost 40% of patients with *JAK2*V617F-positive ET had a reduction in their *JAK2*V617F allele burden, with occasional patients no longer having detectable *JAK2*V617F, leading to their being classified as having achieved a complete molecular remission. Although hematologic remissions were frequently achieved after 3 months of therapy, the effects on *JAK2*V617F were observed after 6 months of treatment. Most patients were successfully treated with 45 to 90 μg/weekly, and 22% of patients ceased therapy because of toxicity. Surprisingly, the hematologic and molecular responses persist for a number of months after discontinuation of therapy, suggesting that intermittent therapy may be an acceptable means of chronically administering this drug. Additionally, molecular responses in a cohort of 31 *CALR*-mutated ET patients treated with peg-IFN-α2b were reported with a baseline allelic frequency of 41% reduced to 26% and two complete responses. Patients with additional subclonal mutations (*TET2*, *ASXL1*, *IDH2*, and *TP53*) were less likely to achieve molecular responses. This is consistent with the finding that patients harboring concurrent mutated *JAK2* and *TET2* can still have evidence of persistent *TET2*, despite complete response of *JAK2*V617F after peg-IFN-α2b therapy. Czech and coworkers noted that the effects of IFN on hematological responses were independent of driver mutational status but that the overall molecular remission rate was 78% for *JAK2*V617F-positive patients and 30% for *CALR*-mutated patients ($P = 0.004$).[25] These data reflect important biological differences between *CALR*-mutated and *JAK2* mutated ET, which might have important therapeutic implications.

Yacoub et al.[26] investigated the outcomes of pegylated-rIFN-α2a therapy in ET patients previously treated with hydroxyurea. The Myeloproliferative Neoplasm Research Consortium (MPN-RC)-111 study was an investigator-initiated, international, multicenter, prospective phase 2 trial which evaluated pegylated-rIFN-α2a therapy in 65 high-risk ET patients that were either refractory or intolerant to hydroxyurea. At 12 months, the overall response rate (complete or partial remission) in ET patients was 69.2%. Complete remission rates were higher in ET patients with *CALR* mutations than without (56.5% vs. 28.0%; $P = 0.01$), however there was no significant effect of pegylated-rIFN-α2 on VAF of the *CALR* mutation. However, pegylated-rIFN-α2a did have an effect on *JAK2*V617F VAF with a median absolute reduction of −6% in patients achieving a CR versus +4% in patients with only a partial response or a nonresponse. There was a significant rate of adverse events with pegylated-rIFN-α2a treatment; most were manageable, with only 13.9% of patients requiring discontinuation of pegylated-rIFN-α2a due to adverse events. There was no major bleeding events, and at 1 year, the cumulative incidence of major vascular events was 2%. The effect of this treatment on disease progression cannot be evaluated due to the limited study period. These investigators concluded that pegylated-rIFN-α2a is an effective therapy for patients with ET who were previously refractory and/or intolerant of hydroxyurea.

To gain a more comprehensive assessment of the clinical usefulness of pegylated-rIFN-α2a in newly diagnosed ET patients, a prospective clinical trial comparing pegylated IFN-α2a with hydroxyurea in patients with high-risk ET and PV was completed at numerous sites in North America and Europe by the MPN-RC. The primary objective of this phase 3 trial was to compare the complete remission rate after 12 months of treatment with either pegylated IFN-α2a or hydroxyurea in newly diagnosed patients with ET, and the secondary objectives were to compare toxicity and tolerability. The overall response rate (complete remissions + partial remissions) at 12 months was 69.8% for hydroxyurea, 78% for pegylated IFN-α2a ($P = 0.22$), and for those patients remaining on trial at 24 months, the overall response rate was 40.7% for hydroxyurea and 59.6% for pegylated IFN-α2a ($P = 0.04$). Pegylated IFN-α2a and hydroxyurea were similar in their effect on spleen size and histopathologic resolution, and both were associated with low incidence of transformation to MF/leukemia and thrombosis. Overall short-term, pegylated IFN-α2a treatment of ET was not found to be superior to hydroxyurea in remission rate or in decreasing symptom burden. However, it was associated with a higher rate of grade (¾) toxicity.

Based on the literature discussed above, we recommend that IFN-α or anagrelide be considered as reasonable alternatives to hydroxyurea in a patient younger than 60 years of age who has had a previous thrombotic episode (see Table 71.7). Which drug should be considered the standard of care in so-called *high-risk patients* remains a topic of debate.

A number of small-molecule inhibitors of *JAK2* have been evaluated for the treatment of ET patients. These agents reproducibly lower platelet counts and have been shown to decrease symptom burden. Harrison et al. evaluated the utility of ruxolitinib in ET patients resistant or intolerant to hydroxyurea in a randomized phase 2 trial of ruxolitinib vs best available therapy in ET. Fifty-eight and 52 patients were randomized to receive ruxolitinib or best available therapy, respectively. There was complete response within 1 year in 27 (46.6%) patients treated with ruxolitinib vs 23 (44.2%) with best available therapy ($P = 0.40$), indicating ruxolitinib did not elicit a better response rate. Similarly, rates of transformation, thrombosis, and hemorrhage were not significantly different at 2 years. There was, however, some improvement in disease-related symptoms in patients treated with ruxolitinib, relative to best available therapy. Patients treated with best available therapy did not experience any grade 3 or 4 anemia or thrombocytopenia, whereas a proportion of ruxolitnib-treated patients did. Based on these findings, it is clear that ruxolitinib is not superior to other second-line treatments for ET. Ruxolitinib is currently not approved for use in ET patients.[27]

The use of platelet antiaggregating agents remains an important area of investigation. Patients with ET have an increased predisposition to hemorrhage, which is likely potentiated by the use of drugs that affect platelet function. Transient ischemic attacks and erythromelalgia associated with ET respond rapidly to aspirin alone. In erythromelalgia, symptoms disappear for 2 to 4 days after the administration of a single dose of aspirin. Although these agents surely have a role in the treatment of these specific complications, their use should be pursued with extreme caution because of the increased risk of hemorrhage. Low-dose aspirin therapy has been uniformly recommended for virtually all patients with ET, independent of their risk of developing a thrombotic event. These recommendations are somewhat surprising because they are based on two clinical trials of the effects of low-dose aspirin therapy in PV patients, and such a trial with aspirin has never been performed with a population of ET patients. An independent analysis of the data from these two trials by the Cochrane Collaboration indicated that the use of low-dose aspirin therapy was associated with a statistically nonsignificant reduction in the risk of fatal thrombotic events and was not associated with an increased risk of bleeding episodes.

After a retrospective study of 198 patients with low-risk ET, Alvarez-Larrán et al.[10] concluded that antiplatelet therapy did not reduce the incidence of thrombotic events and might increase the bleeding risk if platelet counts are greater than 1000×10^9/L or aspirin is used in patients with a bleeding history (Table 71.8). A retrospective study of 433 patients (*CALR* = 271, *JAK2*V617F = 162) with low-risk ET receiving aspirin demonstrated no significant reduction in thrombotic complications but rather an increase in hemorrhagic complications in the *CALR*-mutated cohort (12.9 vs. 1.8 × 1000 patient-years, $P = 0.03$. Interestingly, the presence of *JAK2*V617F and cardiovascular risk factors was associated with a higher risk of thrombosis, which was reduced with administration of aspirin.

Chu et al.[28] also performed a meta-analysis to evaluate the risks and benefits of aspirin therapy in adult ET patients. This systematic review analyzed the benefits and risks of antithrombotic therapy in ET, including 24 observational studies with 6153 patients in total, with most being categorized as high-risk. This analysis highlights the great uncertainty in this area, reporting that the relative risk of thrombosis and bleeding with antiplatelet therapy, compared to without, ranged from 0.26 to 3.48 and 0.48 to 11.04, respectively. They concluded that the presently available evidence for aspirin in adult ET patients was imprecise, inconsistent, and "at best at high-risk of bias." They recommended that randomized studies be pursued in subgroups, perhaps based on their risk for thrombosis, or their driver mutational status. One can only conclude from these studies that the data supporting the universal use of aspirin in ET patients is limited. Most clinicians use aspirin indiscriminately in ET, but this practice requires re-consideration.

Most recently, a randomized double-blind trial assessed the utility of 3 aspirin regimens (aspirin 100 mg one, two, or three times daily for 2 weeks) on platelet inhibition in ET. Dosing of aspirin once daily led to incomplete inhibition in most patients. Twice daily dosing of aspirin improved platelet inhibition, and thrice dosing did not provide any further inhibition).[29] It remains to be determined whether greater inhibition of platelet activity correlates with symptom burden and risk of thrombosis in ET patients.

Aspirin should be used with caution in patients with peptic ulcer disease. Such patients who require aspirin benefit from the concurrent use of a proton pump inhibitor such as omeprazole rather than switching them to clopidogrel. This more critical evaluation of the evidence supporting the indiscriminate use of aspirin therapy in ET patients requires serious reconsideration of this practice. In patients who absolutely require aspirin therapy, one should avoid the simultaneous

TABLE 71.8 **Outcome in Patients With Low-Risk Essential Thrombocythemia Followed With Careful Observation or Treated With Antiplatelet Therapy**

	Observation (848 Person-Years)		Antiplatelet Therapy (802 Person-Years)		*P*
	Events (*n*)	Incidence Rate (95% CI)	Events (*n*)	Incidence Rate (95% CI)

Bleeding	5	6.0 (2.5–14.5)	10	12.6 (6.8–23.4)	0.09

CI, Confidence interval.
From Alvarez-Larrán A, Cervantes F, Pereira A, et al. Observation versus antiplatelet therapy as primary prophylaxis for thrombosis in low-risk essential thrombocythemia. *Blood*. 2010;116(8):1205–1387.

administration of aspirin with a nonsteroidal antiinflammatory drug (NSAID) such as ibuprofen or naproxen because such NSAIDs are known to compete with aspirin for a common binding site on COX-1 that prevents aspirin from gaining access to and acetylating its target serine. Low-dose aspirin therapy must be restricted to patients with platelet counts of less than 1500 × 10^9/L and not be used in patients receiving anagrelide therapy unless they have experienced an arterial thrombotic event. The diagnosis of acquired von Willebrand syndrome should be excluded before aspirin use and considered a contraindication to the use of aspirin.

Whether all patients with low-risk ET should be uniformly treated with aspirin remains speculative because prospective randomized clinical trials including appropriate numbers of patients so as to assure the resolution of this dilemma have not been completed to date.

A continuing clinical controversy revolves around the question of whether any treatment is indicated in patients with ET in whom the platelet count elevation is initially detected fortuitously and who remain largely asymptomatic. In a retrospective study of 99 consecutive low-risk ET patients (age <60 years) who presented with extreme thrombocytosis (platelet count >1000 × 10^9/L) but without a previous history of thrombohemorrhagic complications, the incidence of major thrombosis and hemorrhagic events was shown to be similar during follow-up to those who were treated with prophylactic cytoreductive therapy and those who did not receive such therapy. If the clinician feels compelled to use some therapeutic intervention in young, asymptomatic patients, low-dose aspirin (81 mg/day) appears to be effective in the treatment of microvascular complications, and its use is associated with limited toxicity. Still, it seems reasonable to withhold therapy in younger, asymptomatic patients until the development of a clinically significant thrombotic or hemorrhagic event. Patients older than 60 years of age with other significant risk factors for cardiovascular complications are probably best served by immediate institution of therapy. A sensible strategy for administering aspirin therapy to ET patients was provided by Robinson and Godfrey. Their practice is to provide aspirin therapy to low-risk *JAK2*- and *MPL*-mutated ET patients. However, for low-risk *CALR*-mutated ET patients, they are reluctant to treat them with aspirin due to a lack of evidence available justifying its use given the relatively higher risk of bleeding. They concluded that aspirin is indicated in ET patients with increasing age or with cardiovascular risk factors but should be avoided in patients with platelet counts greater than 1000 × 10^9/L. With a platelet count 1000 to 1500 × 10^9/L, patients are requested to monitor for bleeding or bruising episodes and they should be evaluated for acquired von Willebrand syndrome. If these patients have a major bleeding episode, aspirin should be discontinued immediately and platelet transfusion therapy should be considered if the severity of the bleed merits such an intervention. Aspirin should be withheld in any patient with overt bleeding, including those patients with acquired von Willebrand syndrome; the bleeding in such patients will likely resolve in with normalization of platelet numbers with hydroxyurea. At this time of platelet normalization aspirin therapy can reconsidered.

The management of pregnant patients with ET remains problematic. The major goal of any therapeutic intervention in pregnant patients with ET should be the prevention of the vasoocclusive events that lead to placental infarction; intrauterine fetal growth retardation; and, in some cases, fetal death. Patients with *JAK2*V617F-positive ET are at a higher risk of developing such complications. In one large series, there was no significant relationship between the fetal outcome and the degree of maternal thrombocytosis or the presence of disease complications. In this series, there were no instances of excessive bleeding or other related complications during delivery. This group did not recommend the use of therapeutic plateletpheresis and, in fact, claimed that specific therapy (aspirin, heparin, or plateletpheresis) did not alter the clinical course. Low-dose aspirin (81 mg/day), because of its profound effect on events involving the microcirculation such as erythromelalgia and transient ischemic events, has been used with increasing frequency in pregnant patients during the first and second trimesters. Low-dose aspirin therapy is safe in pregnant women.

It is recommended that aspirin be discontinued at least 1 week before delivery to avoid bleeding complications such as an epidural hematoma during delivery or during the postpartum period. Because of the high-risk of bleeding in patients with platelet counts greater than 1000 × 10^9/L with acquired von Willebrand syndrome, aspirin therapy is contraindicated. There is limited experience with aspirin therapy alone, and although the results are promising, the sample size is too small to confirm a beneficial effect. The observed true birth rate, however, was 75% in those receiving aspirin, compared with 43% in the group in the literature who received no therapy. Aspirin therapy has, however, been found to be ineffective in preventing complications in *JAK2*V617-positive pregnant ET patients. Chemotherapeutic drugs should be avoided during the period of conception and especially during the first trimester. Both hydroxyurea and busulfan are known teratogens in animal models. In addition, busulfan and hydroxyurea reduce fertility in men. Because the greatest risk of thrombosis is postpartum, thrombosis prophylaxis should be initiated in the form of low-molecular-weight heparin and low-dose aspirin after delivery, unless the patient is hemorrhaging. These measures should be continued for approximately 6 weeks. Mothers receiving IFN, anagrelide, or hydroxyurea should refrain from breastfeeding.

IFN-α therapy is not known to be leukemogenic or teratogenic, and because it does not cross the placenta, its use may be considered during pregnancy. The manufacturers of IFN-α still advise that IFN-α not be used during pregnancy because adverse effects on the fetus cannot be ruled out. The effect of IFN-α on male fertility remains uncertain. Schrickel et al.[30] however, have reported a 73.5% live birth rate in 34 high-risk pregnancies in 23 ET patients who had previously experienced a thrombosis, a serious bleeding event, microcirculatory events or extreme thrombocytosis after treatment with IFN. Such promising results should not be dismissed and provide a rationale for IFN therapy in high-risk ET patients during their pregnancy. Anagrelide therapy should be avoided in pregnant patients because of its potential to lead to fetal thrombocytopenia.

Hormone-replacement therapy, including oral contraceptives and estrogen-replacement hormone therapy, remains controversial in patients with ET. Each of these agents in the normal population is associated with an increased incidence of arterial and venous thrombosis. Intuitively, it would seem wise to avoid such agents in patients with ET who are already at an increased risk of developing thrombosis. Gangat et al. retrospectively reviewed the consequences of such hormonal interventions in 305 women. Oral contraceptive therapy was associated with a high incidence of venous thrombosis occurring within the abdominal cavity, but estrogen-replacement hormone therapy in menopausal women did not appear to be associated with an increased incidence of thrombosis. This observation is surprising and might be a consequence of the limited numbers of patients included within this study.

If a patient with ET develops a thrombotic episode, anticoagulation with low-molecular–weight heparin and then transition to an oral anticoagulant is recommended. Vitamin K antagonists such as warfarin have traditionally been the agents of choice in MPN. Treatment of MPN patients with vitamin K antagonists after thrombosis has been shown to result in nearly a threefold decrease in risk of rethrombosis. Recently, the use of direct oral anticoagulants (DOACs) as alternatives to vitamin K antagonists for the prevention of rethrombosis in MPNs has been explored. However, this is limited to small retrospective studies. The DOACs currently in use include Factor Xa inhibitors (apixaban, rivaroxaban, and edoxaban) and the direct thrombin inhibitor dabigatran. Overall, it appears that the use of DOACs prevents rethrombosis to a similar degree as vitamin K antagonists and that risk of bleeding events is not significantly different between these two types of anticoagulants. A study of 442 MPN patients receiving DOACs indicated that dabigtran was associated with a higher risk of bleeding than the other DOACs. It must be noted, however, that these studies are small, heterogenous, and include MPN patients with varying diagnoses. Therefore results are difficult to compare. A randomized trial comparing vitamin K antagonists and DOACs in

MPNs would be necessary to determine the superior anticoagulant class in MPNs, but due to the rarity of the disease and long-term follow-up needed, this is unlikely to be performed. In our practice, we routinely utilize DOACs for prevention of rethrombosis in our MPN patients, finding that adherence to these agents in comparison to warfarin is much more feasible.

A thrombotic episode places a patient into a high-risk group in which myelosuppressive therapy is clearly indicated. Whether patients should have lifelong anticoagulation or should receive only 6 to 12 months of anticoagulation after they are in a complete hematologic remission has not been investigated in a systematic fashion. Because the data necessary to make this decision are not available, this decision can only be made at the discretion of the treating physician. It is our practice and that of many others to continue lifelong myelosuppressive therapy and anticoagulation in those high-risk ET patients with a prior unprovoked thrombotic episode. However in those high-risk ET patients who have had a provoked thrombotic events (surgery, sedentary behavior) it is our practice to discontinue anticoagulation therapy after 12 months but to continue myelosuppressive therapy. Antiplatelet therapy has been shown to reduce the risks of deep venous thrombosis and pulmonary embolism in a variety of high-risk groups. In patients who have a new thrombosis while they are in complete hematologic remission and are optimally anticoagulated, some consideration should be given to adding low-dose aspirin if the risk of hemorrhage is not excessive.

COVID-19 in Essential Thrombocythemia Patients

The incidence of COVID-19 infection in patients with MPNs appears to be relatively low when compared to patients with other neoplasms. However, ET patients infected with COVID-19 appear to be at a particularly heightened risk of complications when compared with PV and MF patients. In a retrospective, multicenter European study of 162 MPN with COVID-19 and all but one patient on low-molecular-weight heparin prophylaxis, ET patients were found to be at a greater risk of developing venous thromboembolism and experiencing mortality from pneumonia than PV and MF patients. Interestingly, COVID-19 infection was associated with a lowering of platelet count in MPN patients, with the greatest reductions being in ET patients. The effectiveness of vaccination in preventing COVID-19 in the MPN population remains to be determined. However, an initial study shows that one dose of the SARS-CoV-2 mRNA vaccine results in an antibody and T-cell response at a high frequency. Further studies are essential to understand the long-term effects of COVID-19 infection in ET patients and the optimal vaccination strategy to prevent infection in these vulnerable patients. At present, we strongly recommend that all ET patients be vaccinated against COVID-19 infection. Although aspirin therapy has been proposed to improve outcomes of normal individuals with COVID-19 infections, a recent meta-analysis indicated that aspirin therapy did not have a protective effect among different groups of patients.

FUTURE DIRECTIONS

ET is a hematologic malignancy with its own distinct clinical manifestations and associated complications. Better means of identifying patients at risk for developing fatal thrombotic or hemorrhagic complications are necessary to provide the basis with which to develop the optimal care of such patients. The ability to reduce the incidence of thrombohemorrhagic episodes with cytoreductive therapy in high-risk patients is well established, yet the optimal agent to employ remains a subject of controversy. The resolution of this dilemma will require a randomized clinical trial that uses clinical events as endpoints and that would require over a decade of follow-up. Whether the resources, both financial and patient numbers, would be available for performing such a trial remains questionable. The use of low-dose aspirin therapy to reduce the number of episodes of erythromelalgia and transient ischemic attacks is widely practiced, but whether aspirin therapy should be indiscriminately used remains a subject of dispute that will only be resolved with the completion of appropriately powered clinical trials. Another pressing question that requires resolution is the degree of reduction of platelet or leukocyte numbers required for optimal management of ET patients. In multiinstitutional trials, pegylated IFN has been shown to be an effective therapy in patients resistant and/or intolerant to hydroxyurea and is also an acceptable alternative to hydroxyurea in high-risk ET patients.

Finally, the discovery of the *JAK2*V617F, *MPL*, and *CALR* mutations has had a major impact on disease classification during routine clinical practice. Diagnostic strategies have now incorporated screening for these driver mutations. This new understanding of the molecular pathogenesis of MPN has led to the development of novel targeted therapies. Now that the clinical phenotype and the risk for disease progression of ET patients are known to be related to not only the ET- related driver mutation but also the burden of additional myeloid malignancy associated mutations, a more personalized approach to treatment options will likely be a goal in the future. This goal will require the discovery of new drugs or therapeutic approaches such as immunotherapeutic strategies.

It is important to note that, at present, a cure for ET is not on the horizon. While current available treatments reduce symptom burden and thrombotic risk, they have not been shown to prevent myelofibrotic or leukemic transformation. Preclinical and clinical evaluation of potential therapies that will target the malignant stem cell are essential for advancement in the care of ET patients.

PERSONAL APPROACH TO THERAPY OF ESSENTIAL THROMBOCYTHEMIA

The optimal therapy for all patients with essential thrombocythemia (ET) remains uncertain. There are currently no therapies that are confirmed to prevent progression of ET to MF or MPN blast phase. The current goal of therapy is to decrease thrombotic risk. Patients with the greatest risk of developing a thrombus have a number of characteristics, including age 60 years or older, history of a thrombotic event, leukocytosis (platelet count ≥11,000 × 10^9/L), and cardiovascular risk factors (hypertension, hypercholesterolemia, diabetes mellitus, obesity). All patients with ET should stop smoking to minimize the risk factors associated with atherosclerotic disease. Indiscriminant use of high doses of nonsteroidal antiinflammatory drugs should be avoided because this practice can lead to an increased risk of hemorrhage. Oral contraceptives should not be used due to their association with a heightened risk of venous thromboembolism. We currently recommend that ET patients receive COVID-19 vaccination.

In high-risk patients, cytoreductive therapy has been shown to lessen the chance of developing additional thrombotic events with the reduction of extreme thrombocytosis to platelet counts below 600,000 × 10^9/L. High-risk patients include patients older than 60 years of age and patients with a history of a previous thrombotic episode, including erythromelalgia, transient ischemic attacks, or large-vessel thrombosis. Even though this treatment philosophy has been considered common practice, the recommendation to treat patients older than the age of 60 years who have not experienced a thrombotic episode with cytoreductive therapy is not based on robust data from multiple randomized trials. Asymptomatic high-risk patients without cardiovascular risk factors may not necessarily benefit from this treatment, and the decision on how to treat them should be based on individual assessment.

Those patients who have venous thromboembolism should be treated with an anticoagulant to prevent rethrombosis. We often initially treat with low-molecular-weight heparin and then switch to an oral anticoagulant, either warfarin or a direct oral anticoagulant. Patients with a provoked thrombosis should receive at least 1 year of anticoagulation, and patients with unprovoked thromboses should receive lifelong myelosuppressive therapy and anticoagulation if the risk-benefit ratio warrants it.

At present, no therapy is indicated in asymptomatic patients younger than 60 years of age. If a patient has a platelet count greater than or equal to 1500 × 10^9/L and acquired von Willebrand syndrome with bleeding symptoms, platelet-reduction therapy is indicated to avoid the high risk of hemorrhage. In totally asymptomatic patients with platelet counts greater than 1500 × 10^9/L, we frequently observe the patients and do not feel compelled to treat them. Patients with acquired von Willebrand syndrome should clearly avoid the use of aspirin.

In patients requiring platelet reduction therapy, the choice among the use of anagrelide, IFN-α, pegylated IFN, or hydroxyurea therapy is based on patient age, ease of administration, and drug-related toxicity. In patients older than 50 years, hydroxyurea or pegylated-IFN therapy is the treatment of choice, but in younger patients, we prefer to initiate therapy with pegylated-IFN. IFN therapy should be avoided in patients with a history of depression, autoimmune disorders, or retinitis. If the patient cannot tolerate IFN or it is not available, we feel comfortable treating symptomatic patients younger than 50 years of age with anagrelide or hydroxyurea. The leukemogenic potential of hydroxyurea appears to be low if not associated with the prior use of an alkylating agent. The development of malleolar ulcers is a frequent complication of hydroxyurea treatment and is a signal for the elimination of hydroxyurea as a therapeutic agent for that particular patient.

Patients who initially receive hydroxyurea and no longer respond to this agent or experience toxicity, thus requiring another agent, should not receive an alkylating agent. This sequence of administration is associated with an extremely high risk of leukemic transformation. Patients who have had a trial of hydroxyurea and require further treatment should receive either IFN-α, pegylated IFN, or anagrelide. Doses of each of these agents required for disease control will, of course, be dependent on the target platelet level that one hopes to achieve. Strict control to a platelet count of lower than 600 × 10^9/L does not appear to be necessary. In these patients, the addition of low-dose aspirin (81 mg/day) should be considered; it is less clear to us if patients who achieve better platelet control with cytoreductive therapy should also be so treated. However, in studies from Europe addressing this question in polycythemia vera, the approach of combining aspirin with cytoreduction therapy appears to minimize thrombotic complications. The use of anagrelide and aspirin in combination should be avoided because of the higher risk of hemorrhage. In patients with thrombotic episodes, especially episodes involving the microcirculation or large vessels, we administer low-dose aspirin (81 mg/day). This dose of aspirin does increase the number of bleeding episodes to a modest degree but is effective in the treatment of thrombotic events. This low-dose aspirin therapy is given in addition to an agent that reduces platelet numbers.

Hydroxyurea can be started at a dose of 1 g/day and then adjusted to achieve the target platelet count (≤600 × 10^9/L) without developing leukopenia. Anagrelide is initiated at 0.5 mg twice daily and increased by 0.5 mg/day every 5 to 7 days if platelet counts do not begin to drop. The usual dose to achieve platelet number control is 2.0 to 2.5 mg/day. Alternatively, combination therapy with anagrelide and hydroxyurea may be considered. Some patients do not tolerate either hydroxyurea or anagrelide. In this patient group, IFN-α therapy with a pegylated form should be given, starting at a dose of 45 mcg/weekly and increasing the dose monthly until a target platelet count is achieved. Patients receiving IFN-α therapy should be closely monitored for adverse events, including yearly ophthalmological examinations as well as mood assessments. Busulfan at 4 mg/day for 2-week courses every time the platelet count rises above the normal range is another therapeutic option. Busulfan therapy is typically reserved for patients older than 70 years of age.

Complications even in young, otherwise healthy patients with platelet counts greater than 2000 × 10^9/L are unusual. However, these marked elevations of platelet numbers can be anxiety-provoking situations for the patient and the clinician.

In certain situations, in young, low-risk patients, treatment should be instituted. Surgery can increase the risk of thrombosis, and the use of anti-inflammatory agents can increase the risk of bleeding postoperatively. Under these circumstances, the platelet count should be lowered to the normal range. In pregnant patients with ET, low-dose aspirin therapy is the first treatment option. If the patient develops symptoms as a result of thrombosis, platelet reduction therapy is necessary, and IFN-α therapy is the treatment of choice.

In a patient with ET and a serious acute hemorrhagic event, the site of bleeding should be determined immediately, and any antiplatelet-aggregating agents should be stopped. Although the platelet count may be high, these platelets should be considered to be qualitatively abnormal, leading to defective hemostasis. The patient may have acquired von Willebrand syndrome. In patients with acquired von Willebrand syndrome, desmopressin (DDAVP) or factor VIII concentrates containing von Willebrand factor can be used immediately at the same time chemotherapy is being administered. If acquired von Willebrand syndrome is not present, the transfusion of normal platelets is suggested. In patients with persistent hemorrhage, immediate reduction of the platelet count can be achieved by plateletpheresis. If this approach fails, some consideration to the use of activated factor VIIa should be given. Hydroxyurea at 2 to 4 g/day for 3 to 5 days should be administered immediately and then reduced to 1 g/day. All patients receiving hydroxyurea should be monitored for the onset of granulocytopenia or thrombocytopenia. Reduction of platelet counts is usually observed within 3 to 5 days of hydroxyurea treatment.

In contrast, patients with acute arterial thrombosis require immediate institution of platelet antiaggregating agents. Aspirin at a dose of 81 mg/day is suggested. Patients with erythromelalgia or transient ischemic attacks will have a rapid cessation of symptoms after the use of low-dose aspirin. In a patient with a life-threatening arterial thrombosis, the platelet count should be lowered with either a combination of apheresis and hydroxyurea or with hydroxyurea alone, depending on the severity of the event. If the arterial thrombosis involves the microcirculation and is not life-threatening (transient ischemic attacks or erythromelalgia), immediate low-dose aspirin therapy is indicated, and platelet-reduction therapy (hydroxyurea, anagrelide, or IFN-α) can be initiated using a standard dose and schedule.

CHAPTER 72

PRIMARY MYELOFIBROSIS AND CHRONIC NEUTROPHILIC LEUKEMIA

Sangeetha Venugopal, Vesna Najfeld, Alla Keyzner, Siraj M. El Jamal,
Ronald Hoffman, and John Mascarenhas

Primary myelofibrosis (PMF) is a Philadelphia chromosome-negative, clonal, myeloproliferative neoplasm (MPN) that is often but not always accompanied by the driver mutations *JAK2V617F*, calreticulin exon 9 (*CALR*), and the thrombopoietin receptor, *MPL515L/K*. PMF is clinically characterized by progressive splenomegaly, cytopenias, and cytokine-driven constitutional symptoms with a propensity for leukemic transformation (20%). Pathologically, PMF is associated with megakaryocyte hyperplasia and atypia, reactive bone marrow (BM) fibrosis, angiogenesis, ineffective erythropoiesis, osteosclerosis, and extramedullary hematopoiesis (EMH), resulting in hepatosplenomegaly. Although there has been exceptional progress in unraveling the complex molecular underpinnings and refinement of the prognostic factors for PMF risk stratification, unfortunately, none of the currently available therapies reliably alters the disease trajectory. Since the last edition of this book, another JAK2 inhibitor, fedratinib, has been added to the therapeutic armamentarium of PMF, which previously included only ruxolitinib. Both these JAK2 inhibitors provide important symptom and spleen relief, but allogeneic hematopoietic stem cell transplantation (HSCT) remains the only curative therapy for PMF. This chapter describes the current understanding of the pathobiology, clinical features, and treatment approaches of PMF.

PHYLOGENY OF THE NOMENCLATURE: PRIMARY MYELOFIBROSIS

PMF was first reported in the literature in 1879, when a German surgeon, Gustav Heuck, described two young patients with massive splenomegaly, circulating nucleated red blood cells (RBCs), and abnormal leukocytes, which he referred to as "splenic-medullary leukemia." He noted that this disease differed from chronic myeloid leukemia (CML) due to the presence of bone marrow fibrosis (BMF), osteosclerosis, and EMH. Since then, several other terms have been used *synonymously* to describe PMF, including angiogenic myeloid metaplasia, myeloid metaplasia with myelofibrosis, and chronic idiopathic myelofibrosis. In 2007, the International Working Group for Myelofibrosis Research and Treatment (IWG-MRT) expert consensus proposed the term PMF to standardize the terminology.

In 1951, William Dameshek included PMF among a group of related disorders, which he termed *myeloproliferative disorders* (MPDs), based on clinical observations of patients with polycythemia vera (PV), CML, and essential thrombocythemia (ET) who developed BM fibrosis and a clinical picture resembling PMF. Additionally, several others described that these disorders originated from a common ancestral cell, reflecting its neoplastic nature. Accordingly, in 2008, the World Health Organization (WHO) modified the terminology from MPD to MPN.[1]

EPIDEMIOLOGY

PMF is rare among the MPNs. Epidemiologic studies have reported a variable incidence of PMF across Europe, Australia, and the United States (US), ranging between 0.5 and 1.3 per 100,000 per year. The annual incidence rate of PMF noted in Olmstead County (MN, USA) was 1.5 per 100,000. Recent Surveillance, Epidemiology, and End Results (SEER) database analysis (2000 to 2016) indicates that the incidence of PMF has remained constant. The median age of diagnosis is 69 years, with most diagnosed between 50 and 69 years of age. PMF is rare in the pediatric age-group. Evidence of genetic transmission does exist: a higher incidence has been reported in Ashkenazi Jews than in Arabs, who both live in Northern Israel, and a familial predisposition to MPNs, including PMF, has been identified. Gender distribution of PMF is reported variably, with some studies reporting male predominance while others do not.

PMF in the United States and Europe is epidemiologically similar, but there are differences in other parts of the world, which may be attributed to environmental exposures. These patients may be younger with an accelerated rate of disease progression. In Japan, PMF is considered a rare disorder. However, the incidence of myelofibrosis (MF) among survivors who were close to the hypocenter of the atomic bomb explosion at Hiroshima and Nagasaki was 18 times higher than the general population of Japan, and they became symptomatic approximately 6 years after the bomb blast. Such data indicate a strong link between excessive radiation exposure and development of PMF, which is further substantiated by the high incidence of PMF in patients who received the contrast material thorotrast (which contains ^{232}Th, a radioactive element with a half-life of 1.41×10^{10} years). Thorotrast is retained indefinitely by the reticuloendothelial cells, resulting in lifelong irradiation to the liver, spleen, lymph nodes, and BM. Less commonly, chronic exposure to industrial solvents (benzene and toluene) is associated with the development of PMF. Unlike PV, where clusters of patients identified in Eastern Pennsylvania raise the concern for possible environmental effects of waste-coal and Superfund sites, no epidemiologic studies definitively support environmental exposure in PMF.

PATHOBIOLOGY OF PRIMARY MYELOFIBROSIS

PMF originates from the pluripotent hematopoietic stem cell, and clonality was first established as early as the 1970s by glucose 6-phosphate dehydrogenase (G6PD) isoenzyme analysis at the post-DNA level, followed by several studies in the 1990s, including an X-linked DNA analysis that revealed a monoclonal X chromosome inactivation pattern in peripheral-blood leukocytes, granulocytes, bone marrow mononuclear cells, and, occasionally, T lymphocytes. The central dogma underlying PMF pathogenesis is based on the concept of a sequential accumulation of acquired genetic or epigenetic alterations within the founder clone population that ultimately drive disease progression and evolution to acute myeloid leukemia. Additionally, the bone marrow niche, megakaryocyte hyperplasia, and the sequent cytokine-induced inflammatory response, as well as aging process, further contribute to the pathobiology of PMF.

Akin to related MPNs, PMF mononuclear cells when cloned in semisolid media generate autonomous erythroid and megakaryocyte colony formation in addition to growth factor-dependent hematopoietic colony growth. Endogenous erythroid and megakaryocyte colonies are a hallmark of abnormal growth of hematopoietic progenitors in vitro, indicative of aberrant hyperactive growth factor signaling. The quest for the genetic basis of autonomous hematopoiesis in MPNs propelled the discovery of *JAK2* V671F in more than 90% of patients with PV and approximately 50% of patients with PMF.[2]

DRIVER MUTATIONS

JAK2 V617F is a gain-of-function mutation in the autoinhibitory domain of the JAK2 tyrosine kinase, resulting in constitutive activation of JAK2 that promotes signal transducer and activator of transcription (STAT)-mediated gene transcription and the resultant autonomous hematopoietic cell proliferation. In a murine transplant model, BM cells transduced with Jak2 V617F resulted in a two-stage MPN clinical phenotype, with the initial stage closely resembling PV with erythrocytosis and neutrophilia, followed by an early MF-like phenotype comprising anemia, thrombocytopenia, splenomegaly, and bone marrow fibrosis.

Furthermore, a small proportion of PMF patients harbor mutations in the lymphocyte adaptor protein (LNK or SH2B3) or Casitas B-cell lymphoma (CBL) genes encoding negative regulators of JAK-STAT signaling. Loss-of-function mutations in *LNK*, predictably result in JAK-STAT hyperactivation, and concomitant mutations in *JAK2* V617F and *LNK* are associated with leukemic transformation of PMF. Gain-of-function mutations in *CBL* are associated with acquired uniparental disomy of chromosome 11q, resulting in homozygous deletion of *CBL* and the resultant loss of its tumor suppressor function. *CBL* mutations occur in 6% of PMF patients and are associated with leukemic transformation. The *JAK2* V617F mutation is homozygous only in 13% of patients with PMF as opposed to 30% in PV, which is attributed to homologous recombination. Homozygosity of *JAK2* V617F in PMF patients is associated with frequent occurrence of unfavorable cytogenetic abnormalities (CGA). Although *JAK2* V617F occurs in almost all patients with PV, a sizeable number of patients with ET and PMF are wild-type for *JAK2*, which led to the pursuit of identifying other mutations that drive hyperactive JAK-STAT signaling.

In 2006, Levine et al., through exome sequencing, identified a somatic activating mutation in the transmembrane domain of the thrombopoietin receptor *MPL* (W515L) in 9% (4/45) of patients with *JAK2* V617F wild-type PMF.[3] *MPL* signals the phosphorylation of both MPL and JAK2/TYK2 and subsequently activates STAT3, STAT5, ERK/MAPK, and PI3K/AKT signaling pathways. In contrast to *MPL* wild-type, the W515L variant promotes ligand-independent JAK-STAT signal activation and confers cytokine-independent growth to 32D, Ba/F3, and UT7 cells. In a murine bone marrow transplant assay, isolated expression of *MPL* W515L led to fully penetrant lethal MPN (18 days) characterized by marked thrombocytosis, splenomegaly, and increased reticulin fibrosis but not erythrocytosis. These data suggest that the *MPL* mutation favors the development of thrombocytosis, but *JAK2* V617F favors erythrocytosis. Compared with wild-type, PMF patients with *MPL* 515L/K are older, severely anemic, and more likely to require transfusion support.

The next breakthrough occurred in 2013, when two groups independently reported frameshift mutations in exon 9 of calreticulin (CALR) in patients with ET and PMF. Approximately 25% of patients with ET and PMF harbor insertion/deletion mutations in *CALR*.[4] Furthermore, 80% of *CALR* mutations fall into either of the two categories: type 1 (52-bp deletion) or type 2 (5-bp insertion). Retrospective studies show that *CALR*-mutated PMF patients present with higher platelet counts, low hemoglobin levels, and leukocyte counts, with a lower thrombotic risk and better overall prognosis than patients with *JAK2* V617F. Studies also implicate a worse prognosis for type 2 *CALR*-mutated patients compared to patients with type 1 mutations.

CALR, located in chromosome 19p13.2, encodes a calcium-binding protein in the endoplasmic reticulum (ER), functions as a chaperone protein and maintains calcium homeostasis. The frameshift mutations in *CALR* exon 9 result in a mutant calreticulin protein with a novel C-terminus sequence lacking the ER-targeting KDEL sequence. The fact that c-MPL is an ER client protein and that *CALR* mutations occurred exclusively in patients with ET or PMF alluded to the possibility that mutant *CALR* somehow activates MPL. Consistent with this observation, *CALR* exon 9 mutation was shown to induce constitutive phosphorylation of JAK2 and activation of STAT transcription only in an MPL-dependent manner.

The extracellular domain of MPL, especially its sites for N-linked glycosylation (CALR binding site), is necessary for the mutant *CALR* to drive transformation. While the glycan-binding sites of *CALR* are crucial for activating MPL, the polypeptide-binding regions and chaperone activity of *CALR* are dispensable. Additionally, positively charged C-terminal residues of mutant *CALR* are necessary for activating MPL signaling; mutation of these residues to uncharged glycine residues abrogates its transforming ability. Of note, truncation of exon 9 terminated the transforming potential of mutant *CALR*, further underscoring the functional importance of the novel C-terminus. Analogously, removal of the 36 most distal residues from the new C-terminus prevented mutant *CALR* from transforming Ba/F3-MPL cells. However, this Δ36 mutant was still able to bind to MPL, suggesting that binding and activation of the receptor may be distinct processes. The exact pathobiological link between the *CALR* mutation and the dysregulated JAK-STAT pathway remains an area of ongoing investigation. Collectively, hyperactive JAK-STAT signaling is central to the pathogenesis of PMF.

Approximately 10% of PMF patients are "triple negative," that is, they lack any of the three driver mutations. Milosevic-Feenstra and coworkers, with whole-exome sequencing, identified noncanonical *MPL* mutations in 11.4% ($n = 70$) and *JAK2* mutations in 8.8% ($n = 57$) of patients with triple negative ET and PMF. These newly identified mutations were heterozygous, and the mutations in *MPL* and *JAK2* were mutually exclusive. 50% of triple negative patients lacked evidence for clonality, but the presence of germ-line mutations indicated that some of these individuals likely had a hereditary rather than an acquired MPN-like disorder. Based on these findings, sequencing of all coding exons of *MPL* and *JAK2* is recommended during the diagnostic work-up of triple-negative ET and PMF patients.

THE ROLE OF EPIGENETIC MUTATIONS IN THE MOLECULAR LANDSCAPE OF PRIMARY MYELOFIBROSIS

With the advent of next-generation sequencing (NGS) technologies, the identification of multiple epigenetic mutations has provided further insight into the complex molecular pathogenesis of PMF and offers rationale for the evaluation of novel targeted therapeutics. Table 72.1 lists the common epigenetic mutations recognized in patients with PMF.[5]

Translocation ten-eleven oncogene family member 2 (*TET2*), located on chromosome 4q24, occurs in approximately 15% of patients with myeloid malignancies. TET2 catalyzes the oxidation of 5-methylcytosine to 5-hydroxymethylcytosine (5hmC), which are key intermediates in DNA demethylation. The resultant DNA hypermethylation affects HSC self-renewal and lineage differentiation. Hematopoietic-specific conditional deletion of Tet2 in mice led to global promoter hypermethylation, increased HSC survival, and a propensity towards chronic myelomonocytic leukemia (CMML)-like phenotype. Furthermore, the Tet2-null (Tet2−/−) background in $Jak2^{V617F}$ mice augments splenomegaly and accelerates the MPN phenotype, suggestive of clonal dominance of Jak2V617F/Tet2−/− double mutants. However, Jak2V617F/Tet2−/− mice did not show increased bone marrow fibrosis or leukemic transformation and

TABLE 72.1 **Acquired Genetic Lesions Identified in Patients With Primary Myelofibrosis**

Gene	Location	Mutation	Frequency
Janus kinase 2 (*JAK2*)	9p24 exon 14	*JAK2V617F*	65%
	9p24 exon 12		Infrequent
Calreticulin (*CALR*)	19p13.2 exon 9	Type 1 (52 bp del) and Type 2 (5 bp in)	25%
Ten-eleven translocation 2 (*TET2*)	4q24		17%
Serine/arginine-rich splicing factor 2 (*SRSF2*)	17q25.1		17%
U2 small nuclear RNA auxiliary factor 1 (*U2AF1*)	21q22.3		16%
DNA methyltransferase 3 alpha (*DNMT3a*)	2p23		15%
Enhancer of zeste homolog 2 (*EZH2*)	7q36.1		13%
Myeloproliferative leukemia virus (*MPL*)	1p34 exon 10	*MPL W515L/K*	5%–10%
Casitas B-lineage lymphoma (*CBL*)	11q23.3	Exons 8 and 9	6%
Splicing factor 3B unit 1 (*SF3B1*)	2q33.1		6%
Isocitrate dehydrogenase (*IDH1* and *2*)	2q33.3/15q26.1		4%
Lymphocyte specific adapter protein (*LNK*)	12q24		Infrequent
Ikaros family zinc finger 1 (*IKZF1*)	7p12		Infrequent
Additional sex Combs-like 1 (*ASXL1*)	20q11.1		10%–20%

resembled chronic phase MF in humans in which *TET2* mutations were associated with increasing age and the presence of *JAK2* V617F did not predict disease severity or survival. Clonality studies in MPN patient samples have failed to define a consistent temporal sequence of acquisition of *TET2* and *JAK2* mutations. These two genetic events appear to occur independently of each other, and *TET2* may even be acquired late in the progression of an MPN. Taken together, there is no evidence at present to show that restoration of TET2 activity may have disease-modifying effects in PMF.

Isocitrate dehydrogenase 1 and 2 (*IDH1/IDH2*), located on chromosome 2q33.3 and 15q26.1, respectively, encode $NADP^+$-dependent enzymes that catalyze the oxidative decarboxylation of isocitrate to α-ketoglutarate in the Kreb's cycle. The neomorphic mutant IDH preferentially transforms α-ketoglutarate to 2-hydroxyglutarate (oncometabolite), the accumulation of which inhibits *TET2* activity. Approximately 4% (12/301) of patients with PMF harbor *IDH1/IDH2* mutations (7 *IDH2* [5 R140Q, 1 R140W, and 1 R172G] and 5 *IDH1* [3 R132S and 2 R132C]) and they can co-occur with *JAK2*, *MPL*, and *TET2*. In patients with *JAK2*-mutated PMF, the presence of *IDH1/IDH2* mutations portends a poor prognosis in terms of leukemia-free survival (LFS) and overall survival (OS). Furthermore, *Idh+/Jak2 V617F+* double mutant transgenic MPN murine model demonstrated augmented blast cell expansion and differentiation arrest, consequently promoting progression to blast phase disease, thereby highlighting *JAK2-IDH1/2* cooperativity in the leukemic transformation of MPN. Retrospective clinical studies have also confirmed the relatively poor outcome of this double mutant subgroup of patients on both OS and risk of leukemic transformation.

The enhancer of zeste homolog 2 (*EZH2*) gene, located on chromosome 7q36.1, encodes a histone methyltransferase (H3K27) and is a catalytic subunit of polycomb repressor complex 2 (PRC2) required for HSC maintenance. PRC2 is a multiprotein enzyme complex (EZH2, SUz12, EED, and YY1) responsible for the trimethylation of lysine 27 on histone H3 (H3K27me3). Additionally, PRC2 can recruit other polycomb complexes, DNA methyltransferases (DNMTs), and histone deacetylases to the gene site, resulting in chromatin compaction and additional repressive activity. Frameshift mutations in *EZH2* resulting in truncated protein isoforms or missense mutations within the highly conserved methyltransferase domain suggest a tumor suppressor role of EZH2. In contrast to Tet2, conditional murine knockout of Ezh2 (Ezh2−/−) in Jak2V617F background rapidly induced bone marrow fibrosis and splenomegaly. While Jak2V617F knock-in mice exhibited a PV-like disease, Jak2V617F/Ezh2−/− mice displayed decreased erythroid differentiation and expansion of megakaryocytic precursors, correlating with peripheral blood thrombocytosis. Given that *EZH2* encodes an H3K27 methyltransferase, loss of EZH2 function reduced H3K27me3 levels, leading to transcriptional activation of target genes, including two proinflammatory cytokine-like mediators, S100a8 and S100a9, as well as high-mobility AT-hook 2 (HMGA2). Thus, loss of EZH2 transcriptional repression in the background of *JAK2* V617F results in a more severe MPN phenotype than *JAK2* V617F alone and favors progression to MF. Approximately 13% of patients with PMF harbor an *EZH2* mutation, which commonly co-occurs with either *JAK2* V617F or additional sex combs-like 1 (*ASXL1*) mutation. Most of these patients exhibited a high-risk phenotype: leukocytosis, increased blast counts, and massive splenomegaly in addition to reduced LFS and OS independent of the dynamic international prognostic scoring system (DIPSS) risk category and *JAK2* V617F allele burden.

ASXL1 mutation occurs in 10% to 20% of patients with PMF, predominantly in those who are triple negative. *ASXL1*, located on chromosome 20q11.1, encodes an enhancer of the trithorax group (trxG) and PRC. The PRC proteins (repress) and trxG proteins (promote) regulate gene expression of homeotic genes, such as *Hox* genes, via histone methylation. *ASXL1* mutations result in loss of PRC2-mediated H3 lysine (H3K27me3) trimethylation. Although conditional deletion of Asxl1 in murine hematopoietic stem cells resulted in progressive anemia and leukemia with multilineage dysplasia akin to human myelodysplastic syndrome (MDS) without myelofibrosis, it is of prognostic importance in PMF. The presence of *ASXL1* is an independent predictor of poor prognosis, and its presence negates the favorable prognosis of *CALR*-mutated PMF. Additionally, the acquisition of an *ASXL1* mutation (approximately 30%) during ruxolitnib therapy is associated with poor outcome at the time of discontinuation of the drug.

Ikaros is a Kruppel-like zinc finger transcription factor integral to normal hematopoiesis and is encoded by the Ikaros family zinc finger 1 (*IKZF1*) gene located at 7p.12. Compared to chronic phase MPNs (0.2%), abnormalities in *IKZF1* occur at a higher rate (21%) of patients with MPN blast phase (MPN-BP), mostly in association with del 7p. IKZF1 is believed to modulate the expression of lineage-specific genes through chromatin remodeling, which results in effective lymphoid development and tumor suppression. Induced *Ikzf1* haploinsufficiency in primary murine stem cells resulted in increased Stat5 phosphorylation and cytokine-dependent growth, suggesting that reduced expression of *IKZF1* is sufficient to perturb growth regulation and that *IKZF1* loss is an important step in the leukemic transformation in a subset of MPN patients.

RNA spliceosome mutations such as Serine and Arginine Rich Splicing Factor 2 (*SRSF2* P95H) and U2 Small Nuclear RNA Auxiliary Factor 1 (*U2AF1* Q157) occur in 14% and 8% patients with PMF, respectively. *SRSF2* mutations cluster with *IDH* mutations and are independently predictive of poor outcomes in terms of shortened LFS and OS. *U2AF1* Q157 occurs primarily in older patients with PMF and is associated with anemia, thrombocytopenia, and inferior survival. In a large series of patients with myelofibrosis that received HSCT, the presence of *U2AF1* mutation was associated with poor survival outcomes.

EXTRAMEDULLARY HEMATOPOIESIS IN PRIMARY MYELOFIBROSIS

Frequently observed peripheral blood abnormalities in PMF are likely attributed to the EMH inherent to this disease. Abnormal CD34$^+$ cell trafficking, preferential homing to the spleen than the marrow, and continuous proliferation of the malignant clone leads to progressive splenomegaly in PMF. The number of CD34$^+$ hematopoietic progenitor cells constitutively mobilized into the blood is dramatically increased in patients with PMF. The number of circulating CD34$^+$ cells in patients with PMF is 360 times higher than in healthy controls and 18 to 30 times higher than in patients with PV or ET. This striking observation led to the suggestion that the quantitation of CD34$^+$ cells in the peripheral blood might serve as a means of discriminating PMF from other MPNs. A level of 15×10^6 CD34$^+$ cells/L in peripheral blood allows differentiation of PMF from PV and ET. The numbers of circulating CD34$^+$ cells tend to increase as the disease progresses, and there is a close correlation between patients presenting with more than 300×10^6 CD34$^+$ cells/L of peripheral blood and imminent evolution to leukemia. These findings suggest that CD34$^+$ cell trafficking abnormality in PMF is caused by the inability of these cells to be retained within the BM or their premature release into the peripheral blood.

PMF is characterized not only by the constitutive mobilization of CD34$^+$ hematopoietic cells but also endothelial progenitor cells. Endothelial progenitor cell mobilization predominates during the prefibrotic phase of PMF, while hematopoietic stem/progenitor cell mobilization occurs characteristically in advanced PMF. This perturbed stem cell trafficking likely results in the seeding of extramedullary sites with primitive hematopoietic and endothelial cells, leading to EMH within the liver and spleen, as well as other organs.

Several proteolytic pathways play a significant role in cytokine-mediated stem cell mobilization. Proteases released by activated neutrophils cleave vascular adhesion molecule-1 (VCAM-1) expressed by stromal cells, disrupting the crucial adhesive interaction between VCAM-1 and very late antigen-4 (VLA-4) expressed by HSCs and progenitor cells. The interaction between stromal cell–, endothelial cell–, and osteoblast-derived stromal cell–derived factor-1 (SDF-1 or CXCL12) and the CXC chemokine receptor-4 (CXCR-4) expressed by HSCs and progenitor cells determine the stem cell trafficking pattern. Proteases, including neutrophil elastase, soluble matrix metalloproteinase-9 (MMP-9), and cell-bound MMP-9, have been shown to play a role in the constitutive mobilization of CD34$^+$ cells in PMF patients. Levels of soluble VCAM-1, a degradation product of VCAM-1, are increased in the plasma of PMF patients, which correlates with the number of circulating CD34$^+$ cells. These proteases degrade the chemokine CXCL12 that plays a role in the retention of CD34$^+$ cells within the BM because the degradation products lack the ability to attract CD34$^+$ cells, thereby favoring their mobilization. By contrast, the levels of intact CXCL12 within the spleen are increased, likely supporting the homing and localization of HPC/HSC to extramedullary sites such as the spleen. Furthermore, CXCR-4 expression by PMF CD34$^+$ cells is epigenetically downregulated, which may account for altered CXCL12–CXCR-4 interactions, participating in CD34$^+$ cell mobilization. This downregulation of *CXCR4* expression can be reversed in vitro by treatment with chromatin-modifying agents. Reduced CD34/CXCR4 expression was shown to be associated with a shorter interval to development of severe anemia, massive splenomegaly, cytopenias, increased circulating CD34-positive blood cells, leukemic transformation and death.

Furthermore, *CXCR4* expression was significantly lower in patients with a higher burden of *JAK2* V617F (allele frequency: 75%) compared with patients with a low allele burden, suggesting a dependence upon the *JAK2* variant allele frequency. Similar degrees of CD34$^+$ cell mobilization are observed in post-ET and post-PV MF as well. Passamonti and coworkers demonstrated a relationship between the degree of constitutive mobilization of CD34$^+$ and *JAK2* V617F allele burden in patients with PV, suggesting that such mobilization may be a consequence of the transition from *JAK2* V617F heterozygosity to homozygosity accompanied by granulocyte activation. Agents targeting proteases responsible for constitutive CD34$^+$ cell mobilization may be a possible therapeutic strategy to prevent EMH in patients with PMF.

Most recently, Abdelouahab et al. explored the crosstalk between JAK2 and CXCL12/CXCR4 signaling pathways in MPN. They demonstrated that JAK2 cooperates with CXCL12/CXCR4 signaling to increase the chemotactic response of human cell lines and primary CD34$^+$ cells through signal crosstalk with the phosphatidylinositol-3-kinase (PI3K) signaling pathway, and JAK2 inhibition abrogated CXCL12/CXCR4 signaling in primary MPN cells. These results suggest that inhibition of this signal crosstalk may further contribute to the therapeutic effect (reduction in splenomegaly) of JAK2 inhibitors.

BONE MARROW FIBROSIS IN PRIMARY MYELOFIBROSIS

While the cell of origin in PMF is the pluripotent HSC, BM fibrosis is secondary to BM stromal cell reaction. BM fibrosis is characterized by collagen and reticulin fibrosis composed of type III and type I collagen, respectively. While collagen fibrosis appears to be characteristic of MPNs and associated with severe disease, reticulin fibrosis may also occur in nonneoplastic conditions and does not clearly correlate with disease severity. Although the exact pathogenesis of PMF is unknown, it appears to be intimately linked with megakaryocyte proliferation, differentiation, and the elaboration of fibrogenic cytokines from the malignant megakaryocyte, its progeny.

The ability of primitive human hematopoietic stem cells to engraft sublethally irradiated immunodeficient mice is the standard surrogate in vivo assay for human HSCs. Peripheral blood (PB)-derived CD34$^+$ HSCs from patients with PMF are capable of engrafting nonobese nondiabetic/severe combined immune-deficient (NOD/SCID) mice and generating clonal cells of multiple hematopoietic lineages. The differentiation program of PMF PB CD34$^+$ cells in the engrafted NOD/SCID mice differed from that of healthy CD34$^+$ cells as they produced increased numbers of CD33$^+$ myeloid cells and CD41$^+$ megakaryocytes but fewer CD19$^+$ B cells. This predisposition to megakaryocyte hyperplasia was further explored by incubating CD34$^+$ cells from patients with PMF, PV, and healthy human volunteers in the presence of stem cell factor and thrombopoietin (TPO). PMF CD34$^+$ cells predictably induced megakaryocyte hyperplasia in vitro, and these megakaryocytes exhibited a delayed apoptotic pattern secondary to overexpressed antiapoptotic factor B-cell lymphoma-extra-large (Bcl-XL) protein. Therefore the megakaryocyte hyperplasia in PMF is likely attributed to the enhanced ability of CD34$^+$ cells to generate megakaryocytes and the concomitant Bcl-xL overexpression, resulting in delayed apoptosis and megakaryocyte accumulation. The megakaryocyte role in the elaboration of BM fibrosis in PMF is further suggested by megakaryocytic hyperplasia with dysplastic megakaryocytes, increased circulating megakaryocytes, and megakaryocyte progenitors; by the association of BM fibrosis and acute megakaryocytic leukemia; and by the presence of MF in gray platelet syndrome, an inherited disorder of platelet α-granules. It has been hypothesized that megakaryocytes in PMF overproduce cytokines involved in collagen fibrosis, neo-angiogenesis, and osteosclerosis.

In PMF, the levels of platelet-derived growth factor (PDGF) and transforming growth factor-β (TGF-β) were 2.0- to 3.0-fold and 1.5- to 3.0-fold higher, respectively, than in healthy controls. However, fibroblast growth factor (FGF) levels were similar in both, suggesting that PDGF and TGF-β not only promote fibroblastic proliferation but also influence the synthesis, secretion, and degradation of extracellular matrix (ECM) components. TGF-β upregulates the expression of fibronectin and collagen types I, III, and IV involved in ECM synthesis and downregulates ECM-degrading enzymes (collagenase), resulting in ECM accumulation and progressive fibrosis. Additionally, cytokines like lipocalin 2 (LCN2) promote bone marrow fibrosis through osteoblast production. Basic FGF (bFGF) is a potent angiogenic factor and mitogen for human BM stromal cells. It may be released or leaked from dysplastic and necrotic PMF megakaryocytes or platelets. These findings suggest that bFGF may also contribute to progressive fibrosis and pronounced angiogenesis frequently observed in PMF. Investigators have suggested that impaired megakaryocyte emperipolesis might underlie this fibrogenic cytokine release mechanism, which is supported by the correlation of BM fibrosis and the degree of abnormal emperipolesis noted in PMF BM biopsies. *Emperipolesis* is defined as the random entry of hematopoietic cells into the cytoplasm of megakaryocytes. Impaired emperipolesis of neutrophils and eosinophils in PMF and extrusion of myeloperoxidase-positive granules by the engulfed neutrophils has been reported. Abnormal P-selectin distribution in megakaryocytes likely accounts for the selective sequestration of granulocytes by PMF megakaryocytes.[6]

Furthermore, the elevation in TPO levels observed in patients with PMF is not due to enhanced synthesis but rather reduced expression of MPL by platelets and megakaryocytes of PMF patients, leading to decreased TPO clearance. In ET and PMF, platelets and megakaryocytes are characterized by lower MPL protein levels, and most of the receptors are immature. Endo-H–sensitive activated *JAK2* promotes cell surface localization and enhances protein levels of MPL through stabilization of the mature endoglycosidase H-resistant form of the receptor. But *JAK2* V617F may promote receptor ubiquitinylation and proteasomal and lysosomal degradation, resulting in reduced expression of *MPL*, suggesting that proteasome inhibitors or *JAK2* inhibitors may restore platelet MPL levels. By contrast, persistent MPL expression by progenitor or stem cells is linked to myeloproliferation. These observations support a model where a decrease in MPL mass in platelets and megakaryocytes results in increased TPO levels, which act on the primitive stem cells, contributing to myeloproliferation.

Vannucchi and colleagues demonstrated that impaired expression of the transcription factor GATA1 might contribute to the development of myelofibrosis and sought to further define the role of megakaryocytes in the development of BM fibrosis using *Gata1*^{low} mutant mouse model. Mutations in the GATA1 functional pathway in human PMF have not been described. However, at the protein level, a large number of the megakaryocytes in the BM of PMF patients are GATA1-negative, suggesting that whatever the genetic defect leading to PMF is, it involves the pathway that affects the posttranscriptional or posttranslational modification of GATA1 in megakaryocytes.

Most recent studies have demonstrated that MPN driver mutations induce a ribosomopathy that decreases GATA1 levels in megakaryocytes, halting their maturation. *Gata1*^{low} mice showed high numbers of immature megakaryocytes and severe bone marrow fibrosis, as is seen in patients with PMF. Furthermore, treatment with an inhibitor of Aurora kinase A (AURKA), a protein overexpressed in MF megakaryocytes, rescued GATA1 expression in these cells, reducing marrow fibrosis in animal models, suggesting GATA1 as a druggable target. AURKA inhibition induced polyploidization, features of maturation, and subsequent apoptosis of megakaryocytes from primary MPN patient samples. This concept was tested with the oral AURKA inhibitor, alisertib, in a phase I trial of 25 MF patients in which forced maturation of megakaryocytes and resolution of bone marrow fibrosis in treated patients was associated with clinically significant spleen and symptom responses (NCT02530619).

Using the *Gata1*^{low} mouse model, Migliaccio and colleagues demonstrated that increased bioavailability of TGF-β plays a significant role in promoting disease progression in MF. Impaired megakaryocyte maturation coupled with high IL-8 expression, in an autocrine fashion, induces megakaryocytes to increase TGF-β, which in turn is responsible for suppressing hematopoiesis by normal HSCs (leading to bone marrow failure) and promoting an MF-HSC-supporting microenvironment in the spleen, facilitating the transition of pre-MF to overt MF. Although TGF-β inhibition completely rescued MF in *Gata1*^{low} mice, it was difficult to target TGF-β due to the lack of specificity and off-target effects. However, the TGF-β1 specific ligand trap AVID200 has made it possible to evaluate this therapeutic concept in the clinic (NCT03895112).

Intrasinusoidal hematopoiesis in the BM is a conspicuous finding in PMF. The BM vascular architecture in PMF is characterized by increased type IV collagen deposits coupled with increased BM microvessel density, resulting in increased blood flow. Vessels from patients with PMF are markedly abnormal and appear as localized vascular nests consisting of numerous short but highly branched and tortuous vessels. Increased BM microvessel density in PMF is probably mediated by α-granules of megakaryocytes as well as several angiogenic growth factors, including overexpressed bFGF and increased serum levels of vascular endothelial growth factor (VEGF). Immunohistochemical methods have confirmed that this increased BM microvessel density in PMF is correlated with increased spleen size and is an independent risk factor for OS.

Osteosclerosis is prominent in PMF, which often manifests clinically as bone pain. Osteosclerosis is a consequence of cytokines released by the neoplastic BM cells or stroma (conditioned and activated) interaction with PMF cells. PMF-associated osteosclerosis can be reversed after HSCT, restoring normal hematopoiesis. In both animal models and patients with PMF, TGF-β and stromal cell-derived osteoprotegerin, a member of the TNF receptor family, play pivotal roles in the development of osteosclerosis. Osteoprotegerin is a decoy receptor for the receptor activator of the nuclear factor kappa-B ligand (RANKL). RANKL is a transmembrane protein expressed on the cell surface of osteoblasts that can be cleaved into a soluble form by proteases. Both soluble and membrane-bound RANKL attach to RANK, a cell receptor expressed by osteoclast precursors to stimulate osteoclastogenesis. RANKL and osteoprotegerin are positive and negative regulators of osteoclast differentiation, respectively. Osteoprotegerin reduces the production of osteoclasts by inhibiting osteoclast differentiation, leading to the development of osteosclerosis. In patients with PMF, it remains unknown if the degree of osteosclerosis is reversed by normalization of levels of osteoprotegerin.

Megakaryocytes are not the only cells capable of releasing cytokines that promote BM fibrosis. Serum levels of macrophage colony-stimulating factor (M-CSF), a cytokine that regulates macrophage development and proliferation, are also elevated in patients with PMF. Monocytes and macrophages from patients with PMF engender and amplify the inflammatory cytokines TGF-β and interleukin-1 (IL-1) over those seen with healthy controls. TGF-β and IL-1 are fibroblast mitogens that promote ECM accumulation. Monocyte adhesion through CD44 appears to induce these fibrogenic cytokines by facilitating monocyte-ECM interaction. The proinflammatory transcriptional factor nuclear factor kappa-B (NF-kB) plays a pivotal role in the elaboration of IL-1 as well as in promoting PMF monocyte adhesion. Most recently, Kleppe et al. through integrated RNA sequencing and ChIP-seq data, demonstrated that the NF-kB-dependent transcriptional network fuels the inflammatory state in MPNs and this transcriptional network in PMF could be successfully targeted by inhibiting bromodomain and extra terminal (BET) proteins of the chromatin reader family and significant anticlonal synergy with combined inhibition of BET proteins and JAK2, which was notable in reversing the MF phenotype of an *MPL*-driven murine model of MF. This concept is being evaluated in a phase II trial of the oral pan-BET inhibitor CPI-0610 with three cohorts of monotherapy, combination therapy with ruxolitinib in inadequate ruxolitinib responders, and as upfront treatment in JAK inhibitor-naïve patients (NCT02158858). Early signs of clinical activity with spleen and symptom benefit, most pronounced in the combination arm are also coupled with anemia responses and reduction in bone marrow fibrosis in approximately one-third of treated patients.

Abnormal cytokine expression in PMF represents an inflammatory response to the disease phenotype that not only contributes to the development of BM fibrosis, osteosclerosis, and increased BM microvessel density but also PMF-associated constitutional symptoms including weight loss, anorexia, pruritus, bone pain, and night sweats. Increased levels of IL-8 and IL-2R closely correlate with constitutional symptoms, leukocytosis, requirement for RBC transfusions, as well as inferior LFS and OS. These observations evoke the possibility that mutational events leading to the malignant transformation of hematopoietic cells in PMF may also lead to the activation of transcriptional programs that promote hematopoietic cell survival and disease progression. Increased cytokine levels may, therefore, not only be responsible for the numerous epiphenomena that occur as a consequence of these malignant cells but also act on the malignant clone, affecting the proliferation and differentiation in differing microenvironments characteristic of the BM and various extramedullary sites, including the spleen. Ultimately, this may increase the risk of disease progression or leukemic transformation.

CLONAL EVOLUTION OF PRIMARY MYELOFIBROSIS

Skoda et al., through next-generation sequencing of 104 genes from a cohort of 197 MPN patients, provided insight into the clonal evolution of the clinical phenotype. Somatic mutations were observed in 90% of patient samples, in which 40% harbored mutations other than *JAK2* V617F and *CALR*. *JAK2* V617F was the most common mutation (69%), followed by *CALR* (15%), *TET2* (12%), *ASXL1* (5%), and *DNMT3A* (5%). The presence of two or more acquired somatic mutations portended a poor outcome and increased risk of leukemic transformation. By contrast, none of the patients with isolated *JAK2*, *MPL*, or *CALR* mutations evolved to MPN-BP. However, the rate of acquisition of new mutations was low when assayed from serial samples (two mutations were detected during a total follow-up of 133 patient-years). Most mutations were present at a low allelic frequency from the time of diagnosis, and in the case of *TP53*, rapid evolution to blast phase occurred with the loss of the wild-type allele either by chromosomal deletion or uniparental disomy. These data argue against the concepts of hypermutability and genomic instability in MF; however, it supports a complex clonal architecture in MPNs, where some individuals may develop a biclonal disease and others, a linear acquisition pattern.

In 50% of *JAK2* V617F-mutated MPNs, the blast cells that represent the progeny of leukemia-initiating clone are *JAK2* V617F-negative, suggesting that leukemia originates from a clone distinct from the *JAK2* V617F-positive clone. This coexistent *JAK2* V617F-negative clone appears to have a higher propensity for leukemic transformation. *JAK2* V617F, therefore, does not appear to be a prerequisite for the leukemic transformation of MPNs, suggesting that additional genetic and epigenetic events are required for full transformation to occur. Single nucleotide polymorphism (SNP) array analysis has shown that genomic alterations occur increasingly at the time of blastic transformation and that no single gene or molecular pathway is sufficient to cause transformation. Acquisition of somatic mutations in *TET2*, *IDH*, *TP53*, and *ASXL1* have all been implicated as genetic events leading to leukemic transformation in MF patients. In general, mutations in *TET2* and *DNMT3A* appeared earlier in the disease course, whereas mutations in *ASXL1*, *EZH2*, and *IDH1* were often acquired after *JAK2* V617F.

A surprising correlation was observed between the phenotype of preceding MPN and the *JAK2* mutational status of the leukemic blasts after transformation. In contrast to *JAK2* wild-type MPN-BP in this setting, evolution to BPs with *JAK2* V617F-positive blast cells is invariably preceded by the evolution of ET or PV to MF. Because of these observations, the myelofibrotic transformation of ET or PV likely represents an accelerated phase of the initial MPN preceded by genetic changes that result in evolution to MF and eventually BP. *JAK2* wild-type leukemia, by contrast, usually arises in patients with chronic-phase PV or ET who have not evolved to MF. Although not universally accepted, some have suggested that these leukemias are therapy-related and are the consequence of the administration of myelosuppressive agents administered during the chronic phase. The reversion from *JAK2* V617F to *JAK2* wild-type in these leukemias is not due to homologous recombination. Two models have been proposed previously to account for the clonal relationship between *JAK2* wild-type BP and its preceding MPN: (1) both the chronic MPN and the MPN-BP arise from a shared pre-*JAK2* V617F founder clone and (2) the chronic MPN and MPN-BP arise from two independent stem cells. The model proposed by Lundberg and colleagues also reflects similar models, incorporating a newer understanding of the phylogenetic ordering of mutated *JAK2* and *CALR* with respect to additional acquired somatic mutations (Fig. 72.1).[7] It is possible that each of these models is viable and operates in different patients.

Studies have shown that triple negative patients with PMF have a shorter LFS as compared with *CALR*-, *JAK2*-, or *MPL*-mutated status. Conversely, CALR-mutated patients are at a lower risk of leukemic transformation compared with triple negative and *JAK2*-mutated cases but not with *MPL*-mutated cases. Optimally, patients should receive a HSCT before the leukemic transformation, as MPN-BP is notoriously resistant to conventional remission induction strategies employed in de novo AML. The median survival after blast transformation is a meager 2.6 months, owing to the patient's age and aggressive biology of this form of leukemia.

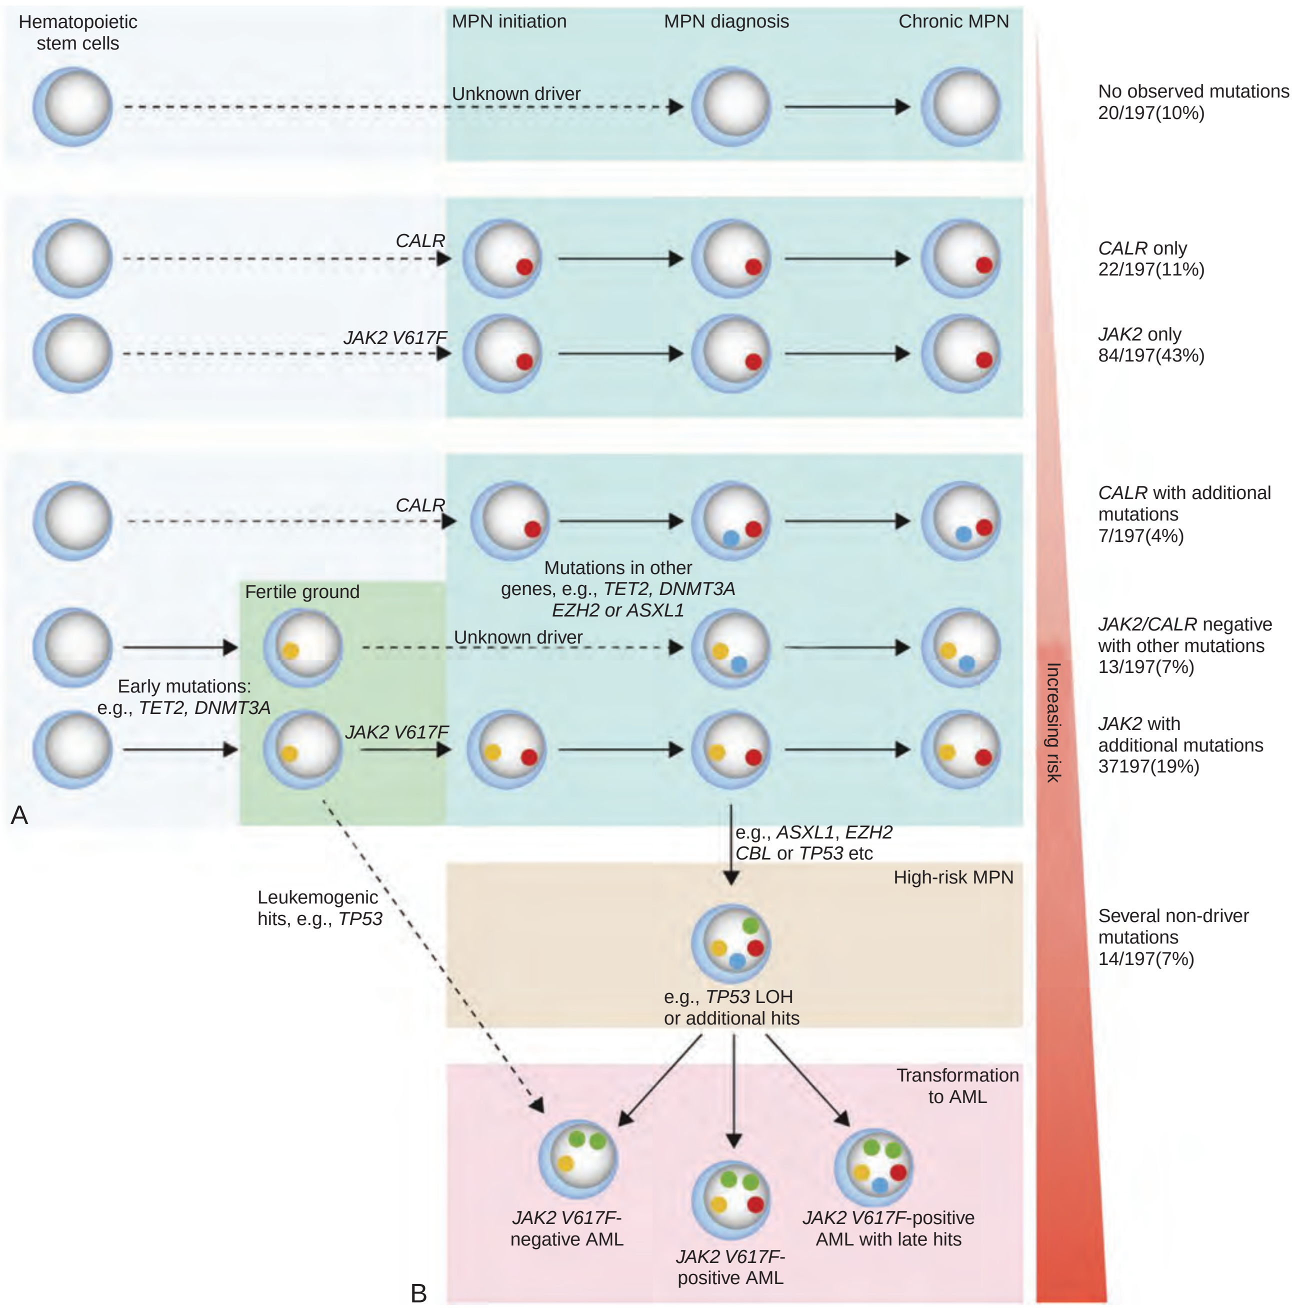
CLINICAL MANIFESTATIONS

Table 72.2 lists the symptoms and physical findings of patients with PMF at presentation.

Approximately 25% are asymptomatic and seek evaluation for incidental splenomegaly or an abnormal blood picture detected on a routine medical exam. Symptomatic patients present with symptoms related to cytokine release or splenomegaly. Cytokine-related symptoms include fatigue, fever, night sweats, bone pain, weight loss, sexual dysfunction, insomnia, difficulties in concentration, and reduced Quality of Life (QoL). Splenomegaly-associated symptoms include a dull, heavy sensation in the left upper quadrant, early satiety, diarrhea secondary to splenic pressure on the intestines or symptoms due to a splenic infarct (left-sided abdominal pain radiating to the left shoulder and fever).

Arterial or venous thromboses occur variably in PMF (10% to 12%). Venous thromboses include cerebral venous sinus thrombosis, splanchnic vein thrombosis, deep venous thrombosis, and pulmonary thromboembolism, while arterial thromboses include stroke, transient ischemic attacks, retinal artery occlusion, myocardial infarction, angina pectoris, and peripheral arterial disease. Established risk factors for thrombosis include the cellular phase of PMF, thrombocytosis (platelet count $>450 \times 10^9$/L), presence of cardiovascular risk factors, Hb greater than 11 g/dL, and *JAK2* V617.[8] The prefibrotic phase of MF (pre-PMF), as defined by WHO 2016 criteria, is associated with a higher thrombotic risk than that associated with ET. In pre-PMF, arterial events occurred at a rate of 1.7% patient-year as compared to venous events of 0.6% patient-year. Although pre-PMF behaves like ET and is managed similarly, retrospective studies have shown that survival of patients with pre-PMF is inferior to that of ET but better than patients with overt PMF. Therefore it is essential to distinguish between ET and pre-PMF in order to inform the patients of their prognosis.

Bleeding diatheses in patients with PMF could be either due to a qualitative or quantitative platelet defect with a heterogeneous clinical presentation, from minor petechiae/ecchymoses to life-threatening bleed, including variceal or intracranial bleed. Thus far, no definitive risk factors have been identified to predict bleeding in patients with PMF except severe thrombocytopenia and excessive thrombocytosis, leading to an acquired form of von Willebrand disease. Patients with pre-PMF are at an increased risk of bleeding when compared to ET and bleeding events occurred at the rate of 1.39 and 0.79 patient-year, respectively. Independent predictors of bleeding in pre-PMF include previous hemorrhage, leukocytosis, an acquired form of von Willebrand disease, and aspirin therapy.



Hematopoietic stem cells
MPN initiation
MPN diagnosis
Chronic MPN
Unknown driver
No observed mutations 20/197(10%)

Figure 72.1 MODEL OF MYELOPROLIFERATIVE NEOPLASM EVOLUTION AND RISK STRATIFICATION IN CORRELATION TO MUTATIONAL EVENTS. In 10% of myeloproliferative (MPN) patients, a driver mutation (*JAK2*, *MPL*, or *CALR*) is not detected. In approximately 50% to 60% of MPN patients, either *JAK2V617F* or *CALR* is found, and this group collectively has a favorable prognosis with a low risk of evolution to acute myeloid leukemia (AML). In patients with mutated *CALR*, additional molecular events appear to occur after this initiating event, whereas in the majority of patients with mutated *JAK2*, similar somatic mutations appear to occur prior to the acquisition of *JAK2V617F*. The presence of additional somatic mutations correlates with an increased risk of disease evolution, and acquisition of *TP53* mutation is associated with development of *JAK2*-mutated or wild-type AML. In model 1 (A), the two phases of disease are phylogenetically related, having arisen from a shared (pre-*JAK2*) founder clone, but in model 2 (B), the two phases of disease are clonally unrelated, reflecting transformation of independent stem cells. *AML*, Acute myeloid leukemia; HSC, hematopoietic stem cell; *LOH*, loss of heterozygosity. *(From Lundberg P, Karow A, Nienhold R, et al. Clonal evolution and clinical correlates of somatic mutations in myeloproliferative neoplasms. Blood. 2014;123:2220.)*

Massive splenomegaly is a prominent clinical finding that occurs in 25% to 50% of patients with PMF, which may be attributed partially to EMH. Palpable hepatomegaly is observed in 40% to 70% of the patients. Non-hepatosplenic EMH can occur in the pulmonary, central nervous, gastrointestinal, and genitourinary systems. The symptoms vary depending on the location of EMH: cough, headache, or paralysis resulting from “brain tumors or spinal cord tumors,” small-bowel obstruction, or intractable ascites. Ascites may be due to either peritoneal or mesenteric implants of EMH or portal hypertension, and if secondary to peritoneal EMH, the exudative ascitic fluid frequently contains myeloid, erythroid, and megakaryocytic elements.

Portal hypertension may be secondary to increased splanchnic blood flow due to splenomegaly and/or intrahepatic obstruction associated with EMH. Complications include ascites or esophageal varices that occur in 9% to 18% of patients with PMF. Occasionally, cirrhosis or evidence of portal or hepatic vein thrombosis has been reported. Nodular regenerative liver hyperplasia occurred in 14.6% of cases and correlated closely with portal vein lesions.

TABLE 72.2 Summary of Symptoms and Physical Findings of Patients With Primary Myelofibrosis Detected at Diagnosis

Symptom or Finding	Incidence (%)
Asymptomatic	16–30
Fatigue	47–71
Fever	5–15
Weight loss	7–39
Night sweats	6–21
Symptoms due to enlarged spleen	11–48
Bleeding	5–20
Gout or renal stones	6–13
Pallor	60
Petechiae or ecchymoses	15–20
Splenomegaly	89–99
Hepatomegaly	39–70
Peripheral edema	13
Evidence of portal hypertension	2–6
Lymphadenopathy	1–10
Jaundice	0–4

Patients with PMF may sometimes present with documented evidence of pulmonary hypertension (progressive dyspnea, signs of biventricular heart failure, elevated pulmonary artery pressures noted in right-heart catheterization), and acutely worsening hepatosplenomegaly. Many succumb to cardiopulmonary complications within 18 months of their initial diagnosis of pulmonary artery hypertension. Pulmonary artery hypertension in this patient subset is likely secondary to chronic thromboembolic disease, EMH within the lung, and elaboration of fibrogenic cytokines from dysfunctional circulating megakaryocytes, or portal hypertension. Patients with primary pulmonary hypertension may have abnormal blood counts (anemia and thrombocytopenia) and BM fibrosis. They can be distinguished from those with PMF by the lack of high levels of circulating CD34$^+$ cells, leukoerythroblastosis, and absence of driver mutations (*JAK2* V617F, *CALR*, or *MPL*).

Renal EMH is uncommon and may present a challenge for diagnosis. Renal EMH manifests mostly as renal dysfunction and proteinuria/nephrotic syndrome. The proteinuria is caused by concurrent glomerular lesions, which is present in most cases of renal EMH. Such lesions include focal segmental glomerulosclerosis, chronic thrombotic microangiopathy, and fibrillary-like glomerulonephritis. Immune complex deposition with subepithelial electron-dense deposits caused by immune dysfunction of PMF is proposed as a pathogenetic mechanism. Renal EMH may be misdiagnosed as tubulointerstitial nephritis due to the presence of eosinophils and their precursors. EMH should be suspected in cases of kidney masses or enlargement in the setting of renal dysfunction or proteinuria

EMH can rarely involve the skin, manifesting as nontender, pruritic red, pink, or violaceous plaques, papules, or hemangioma-like nodules. These dermal infiltrates are composed of combinations of myeloid, erythroid, and megakaryocytic cells. Occasionally, a Sweet syndrome-like picture may precede an overt PMF diagnosis.

Acute monoarticular inflammation caused by secondary gout related to increased cell turnover is seen in 6% of patients. Other physical findings include pallor, icterus, signs of cachexia, moderate lymphadenopathy, peripheral edema, and bony tenderness.

LABORATORY MANIFESTATIONS

Careful examination of the peripheral blood smear and BM (Fig. 72.2) permits a ready diagnosis of PMF. Leukoerythroblastosis with teardrop RBCs (i.e., dacryocytes) strongly suggests this diagnosis. Leukoerythroblastosis is characterized by the presence of nucleated RBCs and immature myeloid elements in 96% of cases. Megathrombocytes and megakaryocytic fragments are frequent findings. The reduction in the number of dacryocytes, postsplenectomy, or chemotherapy initiation has led some to invoke splenic fibrosis as an etiology.

In approximately 60% of patients, hemoglobin levels drop to less than 10 g/dL. The degree of anemia is frequently challenging to estimate through conventional hemoglobin or hematocrit determinations because of dilutional anemia secondary to plasma volume expansion due to massive splenomegaly. Most patients have normochromic, normocytic, and RBC indices. The anemia is a combination of decreased production due to erythroid hypoplasia or ineffective erythropoiesis and shortened RBC survival. Hemolytic anemia in PMF is multifactorial, including hypersplenism, RBC membrane defects resembling paroxysmal nocturnal hemoglobinuria (see Chapter 32), or antierythrocyte autoantibodies. About 5% of patients with PMF may develop iron deficiency anemia secondary to blood loss, either due to GI bleed (variceal bleed or duodenal ulceration), or intravascular hemolysis. Occasionally, a patient with PMF may develop an occult malignancy or a site of EMH within the gastrointestinal tract, which may serve as a bleeding source. Unexplained microcytosis (mean corpuscular volume <80 fL) has been reported in PMF and has not been shown to have prognostic relevance. Macrocytic anemia may complicate PMF. Although folic acid absorption is normal, folic acid deficiency may result from increased cell turnover.

Leukopenia can occur in 13% to 25% of patients, and leukocytosis is seen in one third. Occasional blast cells and granulocytes with the pseudo–Pelger-Huët anomaly are frequent findings. The leukocyte alkaline phosphatase (LAP) score is high in more than half of patients, but low in about one-third, and therefore does not add diagnostic value.

Platelet counts of less than 100,000/mm^3 are observed in 31% of patients, and platelet counts of more than 800,000/mm^3 have been observed in 12%. In pre-PMF, almost 90% of patients had platelet counts higher than 500,000/mm^3 and may develop acquired von Willebrand disease, often posing a bleeding risk. Defective platelet function is common, and platelets frequently do not respond to collagen or epinephrine stimulation. A variety of qualitative platelet anomalies have been documented as abnormal using automated platelet function analyzers such as the platelet function analyzer PF100 or light transmission platelet aggregometry. In 15% of patients, features of ongoing DIC are found, including decreased platelet counts, factor V and VIII, and increased fibrin split products. DIC in PMF is rare but may occur after an invasive surgical procedure.

Additional laboratory abnormalities are quite common. Hyperuricemia frequently occurs as a result of increased cell turnover. In one series, nonspecific elevated levels of lactic acid (95%), bilirubin (40%), alkaline phosphate, and serum glutamic oxaloacetic transaminase (50%) were observed. Patients with PMF have decreased levels of total cholesterol, likely secondary to inflammation and cachexia. The ratio of high-density lipoprotein cholesterol to low-density lipoprotein cholesterol is low.

A variety of immunologic abnormalities have been reported in PMF, including the presence of ANAs, elevated titers of rheumatoid factor, direct Coombs test positivity, lupus-type circulating anticoagulants, hypocomplementemia, BM lymphoid nodules, and increased circulating immune complexes. In one series of 50 patients with PMF, increased quantities of circulating immune complexes were detected in 39% and found to be associated with increased disease activity as manifested by increased transfusion requirements, bone pain, and fever. Some investigators have suggested that abnormalities of the complement system may be significant in the disease

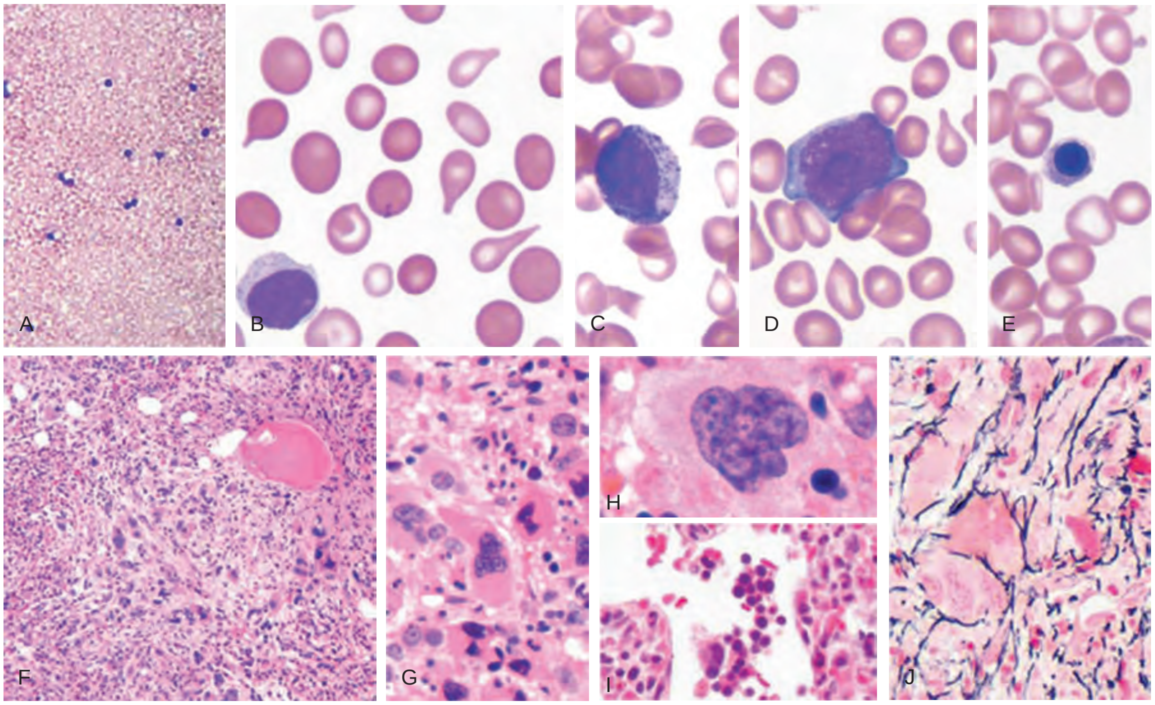

Figure 72.2 PRIMARY MYELOFIBROSIS. Peripheral blood and bone marrow (BM) biopsy. The leukocyte count can vary in primary myelofibrosis from leukopenia to marked leukocytosis. In the case illustrated, the count was normal (A). However, the smear showed numerous dacryocytes, or teardrop forms (B), and a leukoerythroblastic picture (C–E), which is the presence of leukoblasts or immature granulocytic precursors (C), including myeloblasts (D), and circulating nucleated red blood cells or erythroblasts (E). The BM biopsy is frequently hypercellular (F) and comprised of an atypical megakaryocytic and granulocytic proliferation (G) in which some of the megakaryocytes have atypical and pyknotic nuclei. Other megakaryocytes (H) are considered to have nuclei that are "cloud-like." The BM biopsy frequently shows sinusoidal hematopoiesis (I) and significant fibrosis, as illustrated by a reticulin stain (J).

progression of PMF, and others have hypothesized that low levels of C3 may predispose these patients to develop serious bacterial infections.

A remarkably high incidence of monoclonal gammopathies has been reported in PMF, with some series reporting 8% to 10% of benign gammopathies. Several case reports mention concurrent plasma cell or B-cell dyscrasias with PMF.

Successful BM aspiration is unusual, accomplished only in 5% to 10% of cases, with a dry tap in 50% of cases. A BM biopsy is an absolute diagnostic requirement for PMF to determine the presence of atypical megakaryocytes, myeloid hyperplasia, assess the amount of residual hematopoietic cellular tissue, and establish the degree of BM fibrosis. BM biopsies in PMF are typically hypercellular with atypical megakaryocyte morphology and myeloid hyperplasia. The atypical features of the megakaryocytes are paramount in establishing the diagnosis of PMF. Such features include hyperchromasia, high nuclear to cytoplasmic ratio, cloud-like nuclear contour, and tight clustering. Naked megakaryocytic nuclei and open sinuses are fairly common, especially in advanced stages. Although BM fibrosis is expected, prefibrotic PMF lacks this finding (see below). BM fibrosis and osteosclerosis were seen in 67% and 54% of cases, respectively. The characteristic morphologic features include patchiness of hematopoietic cellularity and reticulin fibrosis, with some microscopic fields being cellular and others void of hematopoietic cells. The amount of reticulin may vary from field to field. Additionally, BM biopsies reveal a substantial increase in vascularity. BM microvessels are more tortuous and branched, and the increased microvessel density correlates with increased VEGF expression by megakaryocytes (Fig. 72.3 A and B).

A rare histologic variant, *MF with fatty BM*, is characterized by myeloid hypoplasia associated with fairly complete fat substitution, mimicking the BM of aplastic anemia. These patients frequently have areas of clusters of densely aggregated hematopoietic elements exhibiting the histopathologic characteristics of PMF and large numbers of hematopoietic progenitors circulating in their peripheral blood. This variant of PMF is likely caused by the abnormal trafficking of hematopoietic cells from the BM to extramedullary sites, consistent with the osteosclerosis observed in patients with PMF, increased thickness of some bone units with new lamellae, and focal areas of woven bone. There is a net decrease in osteoclast number and conversion of trabecular pillars into plates.

Currently, pre-PMF is recognized as a distinct type of MPN that is characterized by the absence or presence of minimal BM reticulin fibrosis.[8] Pre-PMF may pose a diagnostic challenge, as clearly differentiating overt PMF from ET may be difficult. However, the myeloid hyperplasia and the tight clustering of megakaryocytes are quite specific for pre-PMF. Progressive fibrosis is frequently observed in such patients as the disease evolves. Based on a careful histomorphometric evaluation of the BM, a progressive fibro-osteosclerotic process paralleled by an increase in numbers of small megakaryocytes with irregular perimeters and megakaryocytes with naked nuclei has been observed during disease evolution. The clinical and morphologic findings of patients with the pre-PMF have been further characterized. Although a steady progression to BM fibrosis has been demonstrated in patients with the prefibrotic phase, fibrosis may remain static or diminish in the more advanced stages of PMF.

Different pathological scoring systems have been used for grading BM cellularity and fibrosis, with the aim of staging and documenting the progression of the disease. The European Consensus Criteria recognized the importance of age-dependent decrease in cellularity (Table 72.3). Grading of MF was simplified using four easily reproducible categories, including differentiation between reticulin and collagen. A consensus was reached that the density of fibers must be assessed in relation to the hematopoietic tissue, which is especially important to avoid a false impression of reduced fiber content in fatty or edematous BM samples after treatment. The progression of BM fibrosis in PMF is accompanied by the expression of subsets of collagenases that is independent of *JAK2* V617F status.

Morphologic examination of the spleen frequently reveals follicular atrophy in the white pulp (Fig. 72.4A) with foci of EMH

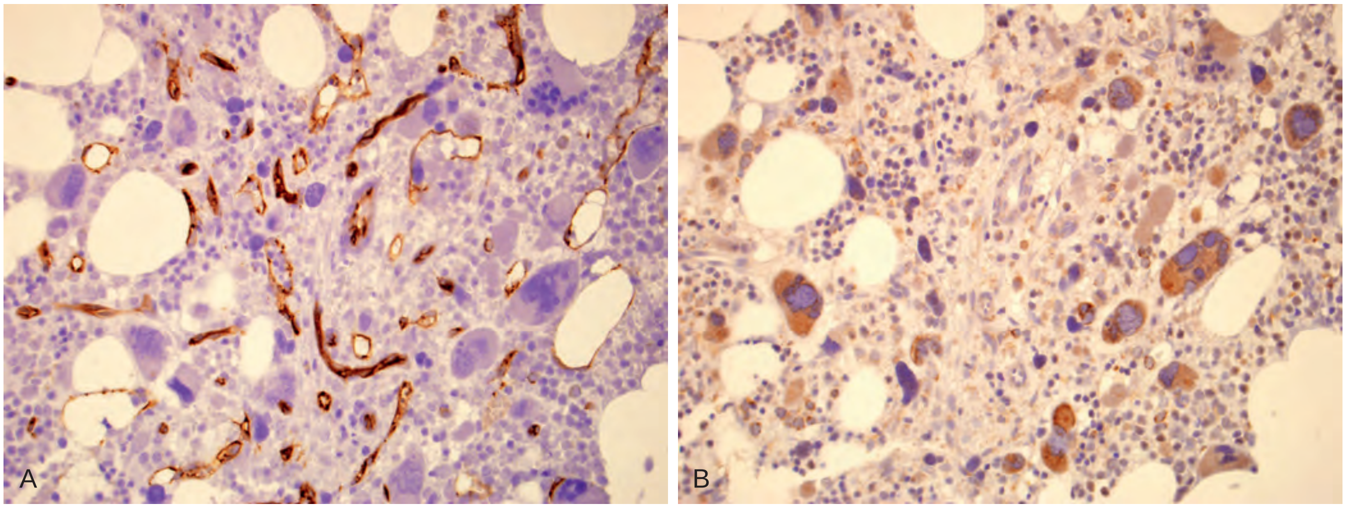

Figure 72.3 IMMUNOHISTOCHEMICAL STAIN OF BONE MARROW BIOPSY FROM A PATIENT WITH PRIMARY MYELOFIBROSIS. The left side shows immunohistochemical stain for CD34 antibody, which highlights the increased microvessel density, as noted with the increased number of vascular structures with the lumen. Please note also the increased number of scattered CD34+ myeloid blasts that are highlighted with granular staining (A). The right side shows immunohistochemical stain for vascular endothelial growth factor (VEGF)C antibody from a matched area of the bone marrow biopsy from the same patient. Note the increased expression of VEGF, as indicated by the brown staining in the cytoplasm of the dysplastic megakaryocytes (B).

TABLE 72.3 **Grading of Myelofibrosis According to the European Consensus Criteria**

Grading	Description[a]
MF-0	Scattered linear reticulin with no intersections (crossovers) corresponding to normal bone marrow
MF-1	Loose network of reticulin with many intersections, especially in perivascular areas
MF-2	Diffuse and dense increase in reticulin with extensive intersections, occasionally with focal bundles of collagen, focal osteosclerosis, or both
MF-3	Diffuse and dense increase in reticulin with extensive intersections and coarse bundles of collagen, often associated with osteosclerosis

[a] The quality of the reticulin stain should be assessed by detection of normal staining in vessel walls as internal control. The degree of myelofibrosis should be assessed by disregarding lymphoid nodules and vessels and by disregarding fibers framing adipocytes. Areas of prominent scleredema or scarring should be included in the overall grading of myelofibrosis. Fiber density should be assessed in hematopoietic areas.

MF, Myelofibrosis.

Data from Thiele J, Kvasnicka HM, Facchetti F, et al. European consensus on grading bone marrow fibrosis and assessment of cellularity. *Haematologica*. 2005;90:1128.

in the sinusoids of the red pulp (see Fig. 72.4B), where megakaryocytes, myeloid elements, and nucleated erythroid elements are seen. The extramedullary hematopoietic cells belonging to each of the myeloid lineages can be distributed in the spleen diffusely or limited to macro nodules. The predominance of immature granulocytic forms is associated with a dismal prognosis. Pathologic examination of the liver reveals hematopoietic cellular elements within the sinusoids. Sinusoidal dilatation is a common finding, as well as prominent intrahepatocyte and Kupffer cell hemosiderin deposition. A marked increase in the hepatic reticulin network has also been observed.

Approximately 50% of patients with PMF harbor karyotypic abnormalities at the time of diagnosis. It is essential to perform appropriate cytogenetic analyses to exclude rare cases of CML with associated BM fibrosis. Because of BM fibrosis, it is often difficult to obtain an optimal number of metaphase cells for cytogenetic analysis. In the past, a substantial percentage of patients with PMF had a “dry tap” or were uninformative, which made the cytogenetic analysis challenging. Although cytogenetic analysis of PMF remains time-consuming and laborious, chromosome studies are now informative in 100% of patients from unstimulated peripheral blood specimens. This success is due to the presence of large numbers of circulating immature mitotic hematopoietic cells (including CD34$^+$ cells) combined with the use of an MPN specific interphase FISH panel and array CGH +SNP that allows for identification of recurrent and novel genomic changes in virtually all patients with MPN (Fig. 72.5). There is a high concordance rate (92%) between conventional cytogenetics and interphase FISH for the 12 most frequent chromosomal abnormalities detected in PMF.

Among the Philadelphia chromosome-negative MPNs, PMF has the highest rate of chromosomal abnormalities at diagnosis. Deletions of the long arms of chromosomes 13 and 20, trisomy 8, and abnormalities of chromosomes 1q, 7q, and 9p constitute more than 80% of all chromosomal abnormalities detected in PMF (see Fig. 72.5), although none is specific to PMF. The deletion of the long arm of chromosome 13 is more frequent in PMF than in PV. Fine FISH mapping has defined the commonly deleted region as 13q13.3–q14.3, encompassing *RB1*, *D13S319*, and *D13S25* loci. As mentioned in Chapter 70, del (20q) and +9/+9p are more frequent in PV than in PMF. Multiple copies of 9p result in trisomy/tetrasomy or amplification of *JAK2*, and each of these abnormalities has been reported in PMF. A 2.7-Mb region on chromosome 20 spanning *D20S108* (proximal) and *D20S481* (distal) is deleted in all Philadelphia chromosome-negative MPNs. A different region is deleted in other myeloid malignancies, but a common 1.6-kb region may constitute the major site responsible for the loss of heterozygosity.

With disease progression from PV/ET to MF, the frequency of CGA is increased up to 100%. Longitudinal studies over a period of 16 years have demonstrated that an increased number of cells with +1q is associated with disease progression. Moreover, loss of 17p13, which leads to a deletion of TP53 in patients with +1q, is associated with perturbations of the TP53 pathway, which contributes to PMF progression. The chromosomal abnormalities observed are similar to those seen at diagnosis of PV/ET or PMF, but through subclonal evolution, they may become very complex. The number of genomic alterations is two or three times greater in the blast phase than it is in the chronic phase. Specific regions on 1q (*MDM4*), 12p (*ETV6*), 17p (*P53*), and 21q (*RUNX1*) are frequently altered and associated with disease progression. The use of comparative genomic hybridization techniques suggests that genomic aberrations are much

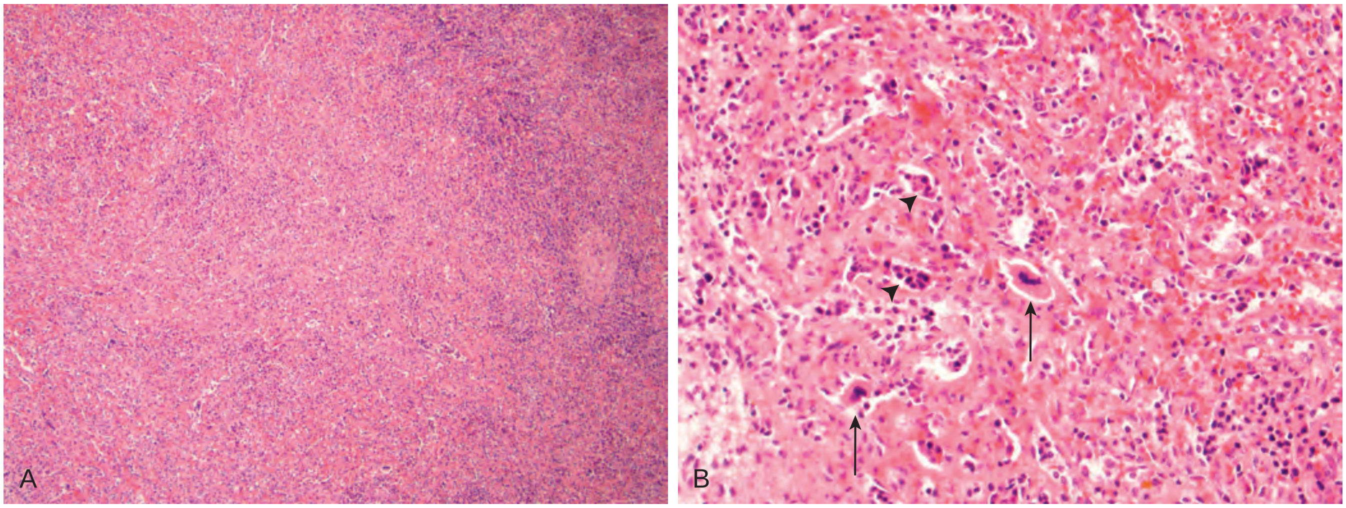

Figure 72.4 SPLEEN MORPHOLOGY IN PRIMARY MYELOFIBROSIS. The left side shows low-power magnification of spleen tissue from a patient with PMF with expanded red pulp and reduced-to-absent white pulp (A). The right side shows higher power magnification with extramedullary hematopoiesis with intrasinusoidal dysplastic megakaryocytes (*long arrows*) and erythroid progenitor clusters (*arrowheads*) along with scattered myeloid cells (B).

more common than what has been previously indicated by conventional cytogenetic analysis and occur in the majority of cases. Even among cytogenetically normal patients with PMF and array CGH+ SNPs, show at least one genomic lesion in 87% of patients. 9p cnLOH occurs in approximately 18% of PMF patients while a gain of 9p and/or cnLOH 9p is present in 88% of cytogenetically normal patients with de novo PMF suggesting that genes located on 9p may play a crucial role in the pathogenesis of PMF. In the majority of patients, CGAs are detected in cells that harbor driver mutations, and single cell analysis has demonstrated that an increased frequency of chromosomally abnormal colonies in *JAK2V617* homozygous progenitor cells may be due to a hyper-recombination phenotype induced by *JAK2V617F*. Others have reported that chromosomal abnormalities such as del(20q), +8, +9 can occur before acquisition of *JAK2V617F* indicating that clonality can also precede acquisition of *JAK2V617*.

Mutational analysis is invaluable in the diagnosis and prognostication of PMF. In PMF, the proportion of patients with *JAK2* V617F in granulocytes has been reported to range from 35% to 95%. The detection rate for *JAK2* V617F is much higher for patients with post-PV MF (91%) than PMF (45%) or post-ET MF (39%). In PV, a high allele burden of the *JAK2* V617F has been associated with an increased risk of evolution to MF. Such differences in allele frequencies are attributed to the variable sensitivity of the diagnostic techniques and differences in the case-mix of the reported series (i.e., the proportion of primary PMF and secondary (SMF) cases). *JAK2* V617F PMF is associated with older age at diagnosis and a history of thrombosis and pruritus. A common *JAK2* germ-line haplotype (46/1) that is identified by the rs12343867 SNP was found to influence susceptibility to developing PMF regardless of *JAK2* mutational status.

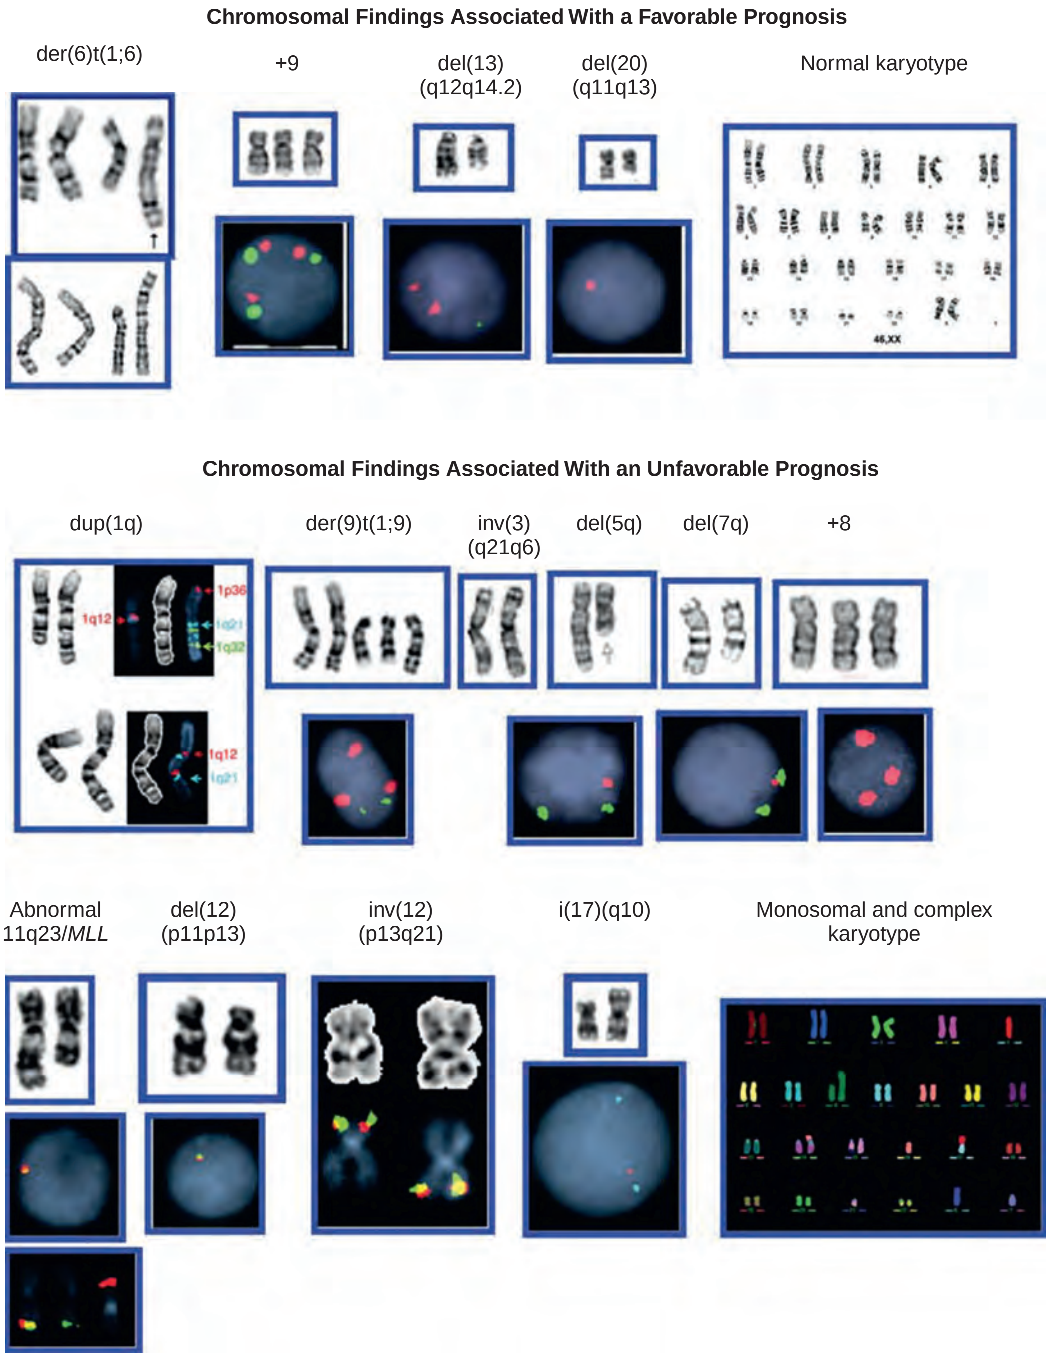
Gain-of-function mutations of MPL, *MPL W515L*, and *MPL W515K* are present in approximately 5% of patients with PMF, 1% with ET, but none with PV. *MPL* mutations may occur concurrently with *JAK2* V617F, suggesting that these alleles may have functional complementation in MPN. In all cases, *MPL W515K/L* VAF is in excess of the *JAK2* V617F VAF. The molecular profile at the time of leukemic transformation of PMF is distinct with a predominance of epigenetic and RNA splicing mutations (*TET2*, *IDH1/IDH2*, *ASXL1*, and *SRSF2*) as opposed to de novo AML in which mutations in the signaling receptor tyrosine kinases (*KIT* and *FLT3)* are common.

The number of circulating cells expressing the CD34 antigen, a phenotypic marker of hematopoietic stem, progenitor cells, and endothelial cells, in patients with PMF is reported to be ≥300-times higher than healthy controls and 18- to 30-times higher than in patients with PV or ET. The clinical utility of the cytofluorimetric measurement of CD34$^+$ cells as a diagnostic marker of PMF is hampered by the observation that a small number of subjects with PMF exhibit a normal number of CD34$^+$ cells in the peripheral blood. Cases with very mild disease or absent or slight reticulin BM fibrosis account for the majority of such patients. High values of CD34$^+$ cells ($>200 \times 10^6$/L) have been proposed as an indicator of an accelerated phase of the disease.

The characteristic radiographic features of PMF include a diffuse increase in bone density and increased prominence of the bony trabeculae. This increased bone density may be patchy and can produce a mottled appearance. Such abnormalities have been reported in 25% to 66% of patients with PMF. Noninvasive imaging of BM is a promising means of evaluating the BM cellularity and distribution in PMF. Magnetic resonance imaging (MRI) can portray the conversion or reconversion of fatty to cellular BM. Fibrotic BM is easily distinguished from cellular BM by its strikingly low signal intensity with all pulse signals. The BM patterns in the proximal femurs of PMF patients are reported to correlate with the clinical severity of the disease. BM MRI has been used to differentiate PMF from ET, where the BM adipose tissue is preserved, but not so in PMF.

DIFFERENTIAL DIAGNOSIS

A patient with hepatosplenomegaly, peripheral cytopenias, teardrop poikilocytosis, leukoerythroblastosis, and BM fibrosis probably has PMF, but other disorders may have a similar clinical picture (Table 72.4 and Fig. 72.6). The WHO diagnostic criteria were revised, incorporating testing for all the driver mutations as well as a greater emphasis on histomorphologic criteria, which allows one to distinguish early phases of PMF and pre-PMF from ET (Table 72.5A). The WHO criteria are based on the recognition of a pre-PMF without reticulin fibrosis and that the primary diagnostic features of PMF are increased megakaryocyte numbers, megakaryocyte morphology, and myeloid hyperplasia (Table 72.5B). SMF frequently occurs in patients with lymphoma or metastatic carcinomas. The clinician should be cautious in making the diagnosis of PMF in a patient who has a history of a primary neoplasm. Demonstration of carcinoma cells in the BM establishes that metastatic carcinoma is the cause of the BM fibrosis (Fig. 72.7A and B). The finding of blastic or lytic bone lesions in patients with MF suggests the presence of an underlying carcinoma. Disseminated tuberculosis and histoplasmosis are associated with the development of SMF corroborated by the presence of caseating or noncaseating granulomas in BM biopsy, which should prompt appropriate microbiological isolation techniques to confirm the diagnosis.



Chromosomal Findings Associated With a Favorable Prognosis

Chromosomal Findings Associated With an Unfavorable Prognosis

Figure 72.5 CYTOGENETIC FINDINGS IN PRIMARY MYELOFIBROSIS. The *top row* shows chromosomal abnormalities and the corresponding interphase fluorescence in situ hybridization (FISH) findings were associated with a favorable prognosis. They include unbalanced translocations between chromosomes 1 and 6 (both the short and long arms of chromosome 6) resulting in a gain of 1q, sole abnormality of chromosomes 9, 13, and 20, as well as the normal karyotype. Abnormalities include a gain of chromosome 9 and interstitial deletions of the long arm of chromosome 13 and 20. Note that gain of 1q and jumping 1q is associated with disease progression to acute myeloid leukemia. The *bottom row* shows chromosomal abnormalities and corresponding interphase nuclei after FISH studies associated with an unfavorable prognosis. They include duplication and trisomy 1q. The most frequent abnormality associated with polycythemia vera-related primary myelofibrosis (PMF) is der (9)t(1;9), resulting in a gain of 1q (*red*) and 9p. Inversion of chromosome 3, -5/del(5q) (*red*), and -7/del(7q) (*red*) are rare in PMF, as are rearrangement of 11q23 and deletion of the short arms of chromosome 12. Sole trisomy 8 is a frequent abnormality associated with PMF, and rearrangements of 12q are almost exclusively identified in PMF. The chromosomal abnormalities associated with the most dismal prognosis are heterozygous 17p loss (*red*) and monosomal or complex karyotype.

Several other primary hematologic disorders can also be accompanied by BM fibrosis (see Table 72.4). MPN–MDS overlap syndromes are frequently seen in clinical practice, and they share clinic-pathological features of both MPN and MDS. These overlap syndromes are characterized by BM hypercellularity, erythroid or myeloid lineage dysplasia, and proliferative features, as well as ineffective hematopoiesis, modest hepatosplenomegaly, and some degree of BM fibrosis. The bone marrow of MDS/MPN overlap syndromes (see Chapter 73) is characterized by dysplastic megakaryocytes rather than the characteristic classic atypical megakaryocytes seen in PMF (hyperchromasia, high n/c ratio, and tight clustering). These patients are occasionally *JAK2* V617F positive and frequently harbor *TET2* mutations. Such patients often present with cytopenias and are at a high risk of developing acute leukemia. These cases indicate the limitations of adhering to strict

TABLE 72.4 Conditions Associated With Myelofibrosis

Nonmalignant Conditions

Multiple myeloma
Systemic mastocytosis
Non-Hodgkin lymphoma
Carcinomas: breast, lung, prostate, stomach

disease classifications and underscore the continuum between MPNs and MDS. The peripheral blood and BM findings that allow differentiation of these disorders can be enhanced by *JAK2* V617F, *MPL W515L/K*, and *CALR* mutational analyses. Patients with the variant MDS with MF frequently present with cytopenias and have dysplastic cellular abnormalities indistinguishable from those with myelodysplasia (see Chapter 61). Their BM, however, is characterized by the presence of BM fibrosis and striking megakaryocytic hyperplasia, with a predominance of small hypolobulated forms, in some cases with striking surrounding fibrosis.

Hairy cell leukemia can also be confused with PMF. In one study, five out of 61 patients who had initially been diagnosed as having PMF were shown retrospectively to have had hairy cell leukemia. Hairy cell leukemia can present as pancytopenia with splenomegaly and is associated with a dry BM tap. In one series, BM reticulin content was increased in 26 out of 29 patients with hairy cell leukemia. The presence of hairy mononuclear cells possessing tartrate-resistant acid phosphatase or the appropriate phenotype in the peripheral blood or BM should facilitate differentiation of PMF from hairy cell leukemia (see Chapter 77). This exercise is essential because of the different modalities of treatment that can be successfully used for hairy cell leukemia.

BM fibrosis can occur in patients with other MPNs, especially PV and CML, and less frequently with ET. In CML, progressive BM fibrosis may herald the onset of accelerated disease or blast crisis. MF in CML occurs in two distinct patterns: one in which patients present with CML and associated BM fibrosis; and a second, in which the MF develops late in the course of the CML (see Chapter 69). The MF in the latter group appears at a mean of 36 months after the diagnosis of CML, is associated with a mean survival time of 4.9 months from the detection of MF, and therefore represents an ominous prognostic sign. In 5% to 15% of patients with PV, post-PV MF occurs approximately 10 years after the initial diagnosis of PV (see Chapter 70). PMF may be clinically and pathologically indistinguishable from post-PV MF except for the prior history of erythrocytosis. Among patients with post-PV MF, 25% to 50% develop MPN-BP, and 70% are dead within 3 years of this transition. Post-PV MF represents a transitional MPN with relatively grave prognostic implications. MF has also been reported after ET and the estimated probability of developing post-ET MF is 3% at5 years after ET diagnosis, 8% at 10 years, and 15% at 15 years.

Acute panmyelosis with myelofibrosis (APMF) represents a clinical entity distinct from PMF (see Fig. 72.6). This disorder has also been termed *acute MF*, *acute myelosclerosis*, *acute megakaryocytic MF*, and *acute myelodysplasia with MF*. APMF is exceedingly rare and corresponds to less than 1% of the cases of AML. Patients characteristically present with pancytopenia, fever, absence of clinically significant splenomegaly, minimal or absent teardrop poikilocytosis, and fibrotic BM. The BM is characterized by the appearance of immature myeloid cells and blast cells, which frequently express the megakaryocytic phenotype. Survival ranges from 1 to 9 months after diagnosis. Its distinction from PMF is vital because aggressive chemotherapy and HSCT are the treatments of choice.

Autoimmune myelofibrosis (AIMF) is another cause of BMF that occurs in patients with autoimmune diseases such as systemic lupus erythematosus and rheumatoid arthritis. AIMF occurs predominantly in females with a broad clinical spectrum. Such patients universally have a positive ANA test result or an elevated anti-DNA titer. Because the physical manifestations of an autoimmune disease may not be evident, all patients with MF should have an ANA test to exclude an autoimmune etiology. An important distinguishing feature is that patients with primary AIMF lack MPN driver mutations and clonality inherent to PMF. AIMF likely represents a distinct clinicopathologic syndrome unrelated to other well-defined autoimmune disorders. Vergara-Lluri and colleagues proposed the following diagnostic criteria that favor AIMF rather than PMF, including: rarity or absence of a leukoerythroblastic reaction in the peripheral blood, absence of peripheral eosinophilia or basophilia, mild degree of BMF (usually MF1), absence of osteosclerosis and bone changes, absence of granulocytic hyperplasia that is seen in PMF, and absence of the characteristic atypical features of the PMF megakaryocytes.

PROGNOSIS

PMF is associated with an estimated median OS of approximately 6 to 7 years (Fig. 72.8). The primary causes of death, in descending order, include leukemic transformation, a progression of PMF, thrombosis and cardiovascular causes, bleeding, and portal hypertension. The incidence of leukemic transformation in PMF ranges between 5% and 22% (Fig. 72.9), with an estimated actuarial cumulative risk of death of 2% and 16% at 1 and 5 years from diagnosis, respectively.

The long-term outcomes of PMF depend on the clinical and cytogenomic features. Based on multivariable analyses, several large studies reported that older age, constitutional symptoms, Hb less than 10 g/dL, leukocytosis, thrombocytopenia, circulating blasts greater than 2%, and transfusion dependency is associated with inferior OS.

Although CGAs are common in PMF, they are nonspecific. However, certain CGAs have an independent prognostic impact on PMF. A Mayo Clinic study developed a two-tier cytogenetic risk stratification model. Patients with a favorable karyotype include chromosome del(13q), del(20q), trisomy 9, isolated or with other single abnormalities, two abnormalities excluding unfavorable abnormalities, and a normal karyotype. The 5-year survival rate was 51%, with a median survival of 5.2 years for patients with a favorable karyotype.

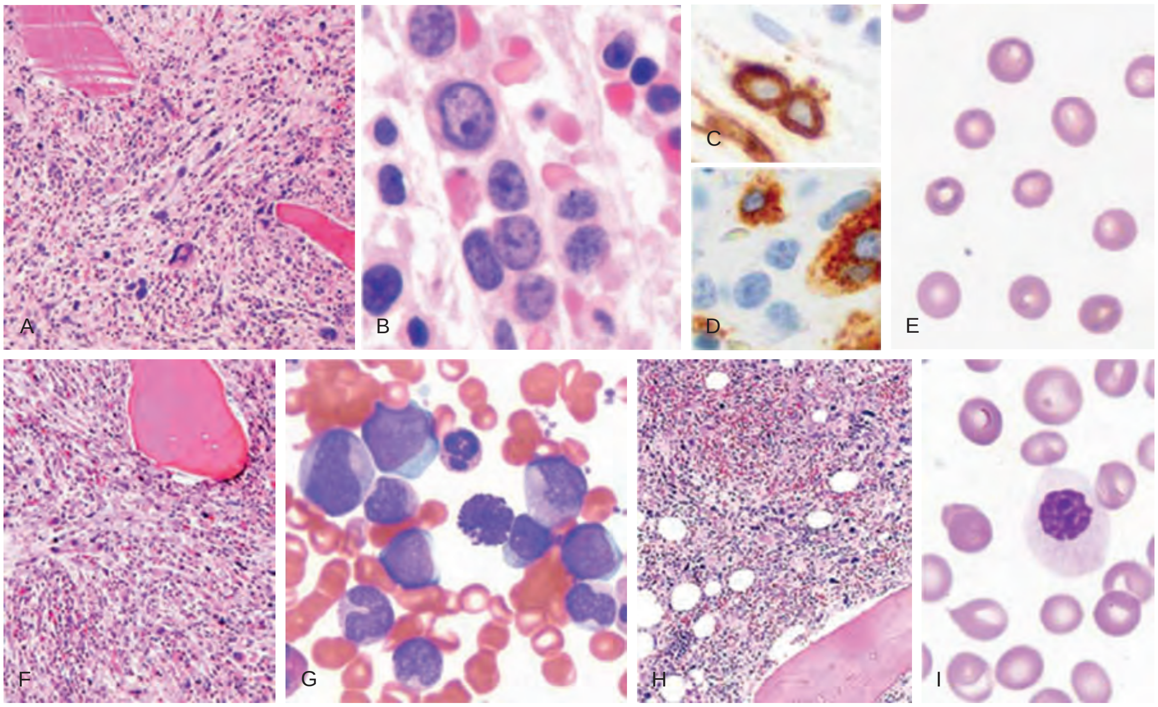

Figure 72.6 DIFFERENTIAL DIAGNOSTIC CONSIDERATIONS IN PRIMARY MYELOFIBROSIS. (A–E) Acute panmyelosis with myelofibrosis (APMF). (F and G) Chronic myelogenous leukemia (CML) in an advance phase with fibrosis. (H and I) Myelodysplastic syndrome (MDS) with fibrosis. The bone marrow (BM) biopsy of APMF, CML in advanced phase with fibrosis, and MDS with fibrosis can all look similar to PMF at low power (A, F, and H). In APMF, the distinction from PMF is made, in part, by seeing increased immature cells on the biopsy (B) interspersed with other hematopoietic precursors. These are usually CD34+ (C), but in contrast to acute megakaryoblastic leukemia are usually CD61– (D). In addition, the peripheral blood usually shows pancytopenia with neither teardrop red blood cells nor leukoerythroblastosis (E). Although the biopsy of CML presenting in an advanced phase can resemble PMF (F), the peripheral blood usually shows classic granulocytosis with left shift and basophilia (G). In the case illustrated, the 30-year-old female patient had fibrotic BM (F) but presented with a white blood cell count of 148,000/L showing a full spectrum of granulocytes, increased blasts (22%), and basophilia. P210 BCR/ABL1 was demonstrated. The bone marrow biopsy in MDS with fibrosis has small megakaryocytes (H), but dysplasia is otherwise difficult to evaluate in the absence of an aspirate, and one must rely on the peripheral blood to identify dysplasia, as in the severely dysplastic neutrophil (F).

A gain of chromosome 1q, which occurs in 22% of PMF patients, is associated with disease progression and jumping 1q translocations with an imminent transformation to AML. In PMF, the region on chromosome 1 that is most frequently duplicated or occurring in trisomy/tetrasomy is between 1q21–32 and 1q32–44 band regions (see Fig. 72.5).

The 5-year survival for patients with an unfavorable karyotype, including abnormalities of chromosomes 5 or 7, inversion of chromosome 3, isochromosome 17q, deletion of 12p or 11q23 rearrangement, as well as a complex karyotype, was 8% with a median survival of 2 years. The 5-year leukemic transformation rates for patients with an unfavorable versus favorable karyotype were 46% and 7%, respectively ($P < 0.0001$). A monosomal karyotype is associated with an unfavorable risk. A monosomal karyotype is defined as having two or more autosomal monosomies or a single autosomal monosomy associated with at least one structural abnormality. This rare CGA is associated with a median survival of 6 months and a 2-year leukemic transformation rate of 29.4%. Evidence suggests that even isolated del(20q), identified in most studies as a marker of favorable prognosis, has been found to promote disease progression through Hippo-kinase *STK4* downregulation as a result of deleted q11 segment on chromosome 20. In patients with *JAK2* 617 F mutation and del(20q) haploinsufficiency of *STK4* gene results in dysregulated inflammatory cytokine production, including IL-1β and IL-6 and disease progression.

The molecular profile of PMF plays a central role in the risk prognostication of PMF and the risk differs according to the presence or absence of driver mutations, in particular *CALR* or high molecular risk mutations (HMR). Triple negative patients displayed significantly worse survival (2.3 years), compared with *CALR-* (15.9 years), *JAK2-* (5.9 years), or *MPL-* (9.9 years) mutated patients. Conversely, survival was significantly better in *CALR*-mutated patients, compared with triple negative (HR, 5.1) and *JAK2-* (HR, 2.5) mutated cases, and no difference in survival rates was observed between *CALR-* and *MPL*-mutated PMF. Guglielmelli and colleagues identified that HMR mutations adversely affect the prognosis of PMF and that outcomes worsen proportionately with the number of HMR mutations. HMR mutations include *ASXL1, SRSF2, U2AF1*Q157*, EZH2*, and *IDH1/2* that occur in descending order of frequency in patients with PMF and the median survivals for those with none, one, or two or more mutations in these genes, were 12.3, 7.0, and 2.6 years, respectively. Additionally, *ASXL1, SRSF2*, and loss of heterozygosity for *TP53* were associated with inferior LFS in patients with PMF.

EVOLUTION OF PROGNOSTIC MODELS IN PRIMARY MYELOFIBROSIS

Prognostication of patients into different risk categories allows us to choose appropriate risk-adapted therapy. In 1996, Dupriez and associates developed the Lille scoring system that stratified patients into three risk categories based on hemoglobin level (<10 g/dL) and leukocyte count (<4000/mm^3 or more than 30,000/mm^3) with a median survival of 93, 26, and 13 months in the low (score-0), intermediate (1), and high (2) categories, respectively. Subsequent studies showed that the Lille score did not discriminate between the intermediate- and high-risk patient groups.

In 2009, the IWG-MRT developed an international prognostic scoring system (IPSS) based on the clinical characteristics of 1054 patients with PMF.[9] Tables 72.6 and 72.7 compare the six validated prognostic scoring systems for patients with PMF. The median OS for this group was 69 months, and the multivariate analysis obtained at a diagnosis-identified age greater than 65 years, presence

TABLE 72. 5A World Health Organization Criteria for Primary Myelofibrosis[a]

Major Criteria

1. Presence of megakaryocyte proliferation and atypia,[b] usually accompanied by either reticulin or collagen fibrosis
2. Not meeting WHO criteria for ET, PV, *BCR-ABL1*⁺ CML, myelodysplastic syndromes, or other myeloid neoplasms
3. Demonstration of *JAK2*, *CALR*, or *MPL* mutation or in the absence of these mutations, presence of another clonal marker[c], or absence of reactive myelofibrosis[d]

Minor Criteria

1. Leukocytosis $\geq 11 \times 10^9$/L
2. Increase in serum lactate dehydrogenase level above upper normal limit of institutional reference range
3. Anemia not related to a comorbid condition
4. Palpable splenomegaly
5. Leukoerythroblastosis

[a] Diagnosis requires meeting all three major criteria and one minor criterion.

[b] Small-to-large megakaryocytes with an aberrant nuclear-to-cytoplasmic ratio and hyperchromatic, bulbous, or irregularly folded nuclei and dense clustering.

[c] In the absence of any of the 3 major clonal mutations, the search for the most frequent accompanying mutations (e.g., *ASXL1*, *EZH2*, *TET2*, *IDH1/IDH2*, *SRSF2*, *SF3B1*) are of help in determining the clonal nature of the disease.

[d] BM fibrosis secondary to infection, autoimmune disorder, or other chronic inflammatory conditions, hairy cell leukemia or other lymphoid neoplasm, metastatic malignancy, or toxic (chronic) myelopathies.

CML, Chronic myeloid leukemia; *MDS*, myelodysplastic syndrome; *PV*, polycythemia vera; *WHO*, World Health Organization.

Modified from Arber DA, Orazi A, Hasserjian R, et al. The 2016 revision to the World Health Organization classification of myeloid neoplasms and acute leukemia. *Blood.* 2016;127(20):2391–2405.

TABLE 72.5 B World Health Organization Criteria for Prefibrotic or Early-Stage Myelofibrosis (Pre-Primary Myelofibrosis)

Major Criteria

1. Megakaryocytic proliferation and atypia, without reticulin fibrosis > grade 1, accompanied by increased, age-adjusted bone marrow cellularity, granulocytic proliferation, and in many cases decreased erythropoiesis
2. Criteria for BCR-ABL1-positive chronic myeloid leukemia, polycythemia vera, essential thrombocythemia, myelodysplastic syndrome, or other myeloid neoplasm not met
3. JAK2 V617F, CALR, or MPL mutation or presence of another clonal marker or of minor reactive reticulin fibrosis in bone marrow[a]

Minor Criteria

1. Anemia not attributed to a coexisting condition
2. Leukocytosis (≥11,000 cells per cubic millimeter)
3. Palpable splenomegaly
4. Lactate dehydrogenase level above upper limit of normal of institutional reference range

[a] In the absence of any of the three major clonal mutations, a search for other mutations associated with myeloid neoplasms (e.g., ASXL1, EZH2, TET2, IDH1, IDH12, SRSF2, and SF3B1 mutations) may be helpful in determining the clonal nature of the disease. Minor (grade 1) reticulin fibrosis caused by infection is noteworthy, as are autoimmune disorders or other chronic inflammatory conditions, hairy cell leukemia or other lymphoid neoplasms, metastatic cancer, or toxic (i.e., chronic) myelopathies.

Modified from Arber DA, Orazi A, Hasserjian R, et al. The 2016 revision to the World Health Organization classification of myeloid neoplasms and acute leukemia. *Blood.* 2016;127(20):2391–2405.

of constitutional symptoms, hemoglobin below 10 g/dL, leukocyte count above 25×10^9/L, and 1% or higher peripheral blood blasts as significant risk factors. Based on the presence of 0 (low risk), 1 (intermediate risk-1), 2 (intermediate risk-2) or greater than or equal to 3 (high risk) of these variables, four discrete risk groups with non-overlapping survival curves were delineated with a median survival of 135, 95, 48, and 27 months, respectively. Although the presence of *JAK2* V617F was associated with age older than 65 years, it did not influence survival in this study. The presence of CGA, most notably the gain of 1q, influenced the survival of the intermediate-risk groups only.

Subsequently, a cohort of 525 PMF patients was followed over time to assess the prognostic influence of the five IPSS clinical variables acquired during the course of disease rather than at diagnosis. The IPSS variables were analyzed as time-dependent covariates in a multivariate Cox proportional hazard model. Anemia was found to have the most significant hazard ratio (HR) for survival and hence a greater weight. Comparing IPSS and DIPSS, the time-dependent analysis confers a higher prognostic power to anemia because anemia is acquired most frequently and earlier during follow-up. The advantage of DIPSS is its ability to assess the real-time prognosis of patients with PMF. The DIPSS-plus further refined DIPSS with the incorporation of an unfavorable karyotype, platelet count below 100×10^9/L, and transfusion-dependent anemia. A poorer LFS was predicted by the presence of thrombocytopenia or an unfavorable karyotype with a 10-year risk of 31% (HR: 3.3; 95% confidence interval [CI]: 1.9 to 5.6).

With expanding understanding of the molecular pathogenesis of PMF and identification of HMR mutations as independent prognostic variables, the genetically inspired prognostic scoring system (GIPSS) and mutation-enhanced international prognostic scoring system plus karyotype, version 2.0 (MIPSS70+ v2.0) were developed. The GIPSS incorporates only mutation and karyotype data. The GIPSS confirmed the independent prognostic relevance of very high-risk (VHR) karyotype (single or multiple abnormalities of −7, inv(3), i(17q), del(12p), del(11q), and autosomal trisomy other than +8 or +9), unfavorable karyotype (other than normal karyotype or sole abnormalities of del(20q), del(13q), +9, chromosome 1 translocation/duplication or sex chromosome abnormality, including loss of Y chromosome), and specific mutations including the prognostically favorable type 1/like *CALR* mutation and the unfavorable *ASXL1*, *SRSF2*, and *U2AF1* Q157 mutations. Based on HR-weighted risk points, a four-tiered GIPSS model was devised: low (zero points), intermediate-1 (1 point), intermediate-2 (2 points), and high (≥3 points); the respective median survivals were 26.4, 8.0, 4.2, and 2 years in an international cohort of 641 cytogenetically annotated patients with PMF.

Prognostic models for transplant-age patients (≤70 years) named the MIPSS70 (mutation-enhanced international prognostic scoring system) and MIPSS70+ (karyotype-enhanced MIPSS70) have been developed. MIPSS70 considered six clinical risk variables (hemoglobin < 10 g/dL; leukocytes $>25 \times 10^9$/L; platelets $<100 \times 10^9$/L; circulating blasts ≥2%; bone marrow fibrosis grade ≥2; and constitutional symptoms), five HMR mutations (*ASXL1*, *SRSF2*, *EZH2*, *IDH1*, and *IDH2*), and one favorable mutation (*CALR* type 1/like). MIPSS70+ considered the same list of mutations but only three clinical risk factors (hemoglobin <10 g/dL, circulating blasts ≥2%, and constitutional symptoms), in addition to a two-tiered cytogenetic risk variable (unfavorable *vs* favorable). These clinical and genetic risk factors were used to compose three risk categories for MIPSS70 (low, intermediate, and high) and four risk categories for MIPSS70+ (low, intermediate, high, and very high).

However MIPSS70+ model did not distinguish between VHR and unfavorable karyotype; furthermore, *U2AF1* Q157 mutation was newly deemed HMR and new sex- and severity-adjusted hemoglobin thresholds defined by hemoglobin levels of less than 8 g/dL in women and less than 9 g/dL in men, and moderate anemia, defined by hemoglobin levels of 8 to 9.9 g/dL in women and 9 to 10.9 g/dL in men were identified. Therefore MIPSS70+ was revised to MIPSS70 + version 2.0.c.

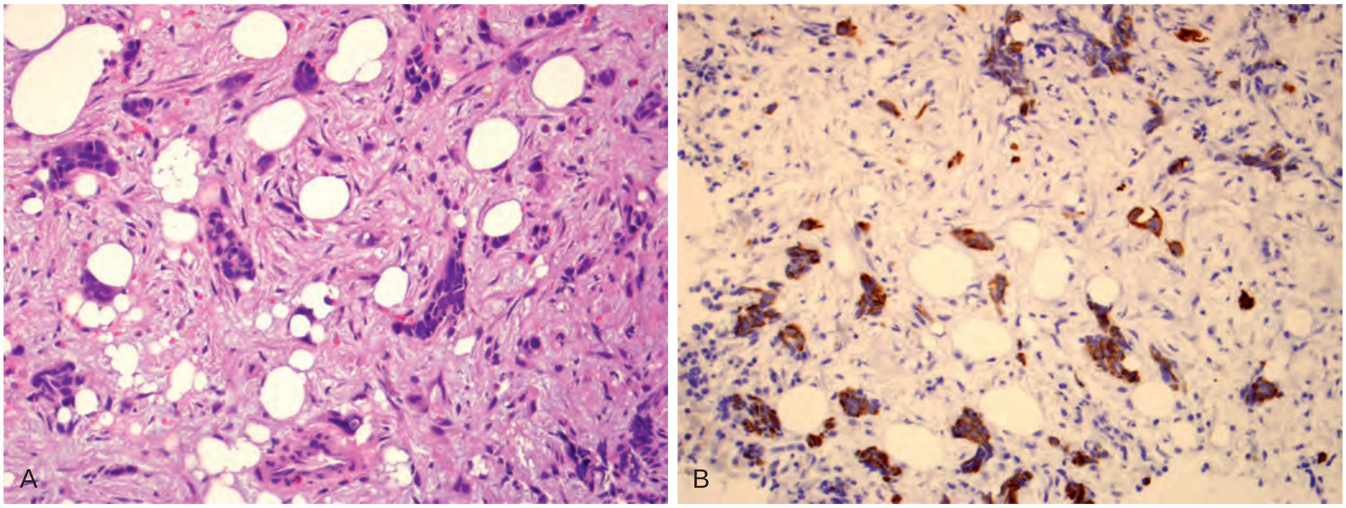

Figure 72.7 Metastatic carcinoma to the bone marrow is often associated with bone marrow fibrosis, as noted in this hematoxylin and eosin-stained section with clusters of carcinoma cells (A) that are highlighted by cytokeratin immunostain (B).

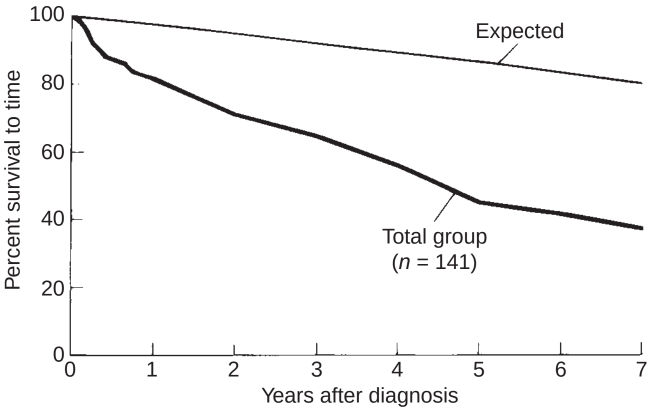

Figure 72.8 OVERALL SURVIVAL FROM THE TIME OF DIAGNOSIS OF 141 PATIENTS WITH PRIMARY MYELOFIBROSIS. *(Data from Silverstein MN. Agnogenic Myeloid Metaplasia. Acton, MA: Publishing Sciences Group; 1975:197.)*

In the multivariable analysis of clinical and molecular characteristics of 406 patients with PMF, HRs were 5.9 and 2.6 for VHR and unfavorable karyotypes, respectively; 2.6 for ≥2 HMR mutations; 1.8 for one HMR mutation; 2.1 for the absence of type 1/like *CALR* mutation; 1.9 for constitutional symptoms; 1.9 and 1.5 for severe anemia and moderate anemia, respectively; and 1.5 for circulating blasts ≥2%. HR-weighted risk points were subsequently allocated to VHR karyotype (4 points), unfavorable karyotype (3 points), ≥2 HMR mutations (3 points), one HMR mutation (2 points), absence of type 1/like *CALR* mutation (2 points), presence of constitutional symptoms (2 points), severe anemia (2 points), moderate anemia (1 point), and ≥ 2% circulating blasts (1 point). This resulted in a new five-tiered MIPSS70+ v2.0 prognostic model: VHR ≥ 9 points; high risk-5 to 8 points; intermediate risk-3 to 4 points; low risk-1 to 2 points; and very low risk-zero points. MIPSS70+ v2.0 further refined low risk to low and very low risk; high to high and VHR. The 10-year median survival was not reached in patients with very low and low risk, but for intermediate-, high-, and very high-risk patients, the median survival was 10.3, 7, 3.5, and 1.8 years, respectively.

Most recently, Nangalia et al., using whole-exome sequencing (WES) of 69 myeloid malignancy genes, developed a personalized genomic prognostic risk model for patients with MPNs.[10] In a large cohort of 2035 patients (ET-1321, PV-356, PMF-309, others—49), 45% harbored *JAK2*, *CALR*, or *MPL* mutations as the sole abnormality. They used Bayesian modeling to identify genomic subgroups of MPNs with maximum within-group similarity and maximum between-group discrimination. *TP53* mutations, often co-occurring with aberrations at chromosome 17p, and deletions at chromosome 5q form the first genomic subgroup; this group had a worse prognosis with a higher risk for leukemic transformation and early death, regardless of the initial driver mutation. The second subgroup was defined by the presence of one or more mutations in 16 myeloid malignancy genes, especially chromatin and spliceosome regulators, loss of heterozygosity at chromosome 4q, and aberrations in chromosomes 7 and 7q. These patients were at increased risk for development of myelofibrosis and shorter event-free survival (EFS) regardless of the MPN subtype and initial driver mutation. The remaining six groups were classified according to their dominant MPN phenotypic driver mutation. These eight genomic subgroups showed distinct clinical phenotypes, including blood counts, risk of leukemic transformation, and EFS. Integrating these clinical and genomic variables, they created multivariate, multistate prognostic models that could generate a personally tailored prognosis. The predicted and observed outcomes correlated in the training as well as in an independent external validation cohort. This model will be most useful for intermediate-risk patients as it allows more informative predictions in a group with otherwise uncertain outcomes.

MANAGEMENT OF PRIMARY MYELOFIBROSIS

The decision to treat an individual patient is based on a comprehensive assessment of the patient’s clinical characteristics, performance status, and prognosis. While “wait and watch policy” is adopted for low-risk patients, most patients with intermediate-/high-risk disease need therapy.

In general, therapy is indicated in the following situations: systemic symptoms (fevers, night sweats, bone pain, and weight loss), splenomegaly-related symptoms including portal hypertension, symptomatic anemia, life-threatening thrombocytopenia, increasing blast cell numbers in the peripheral blood, and hyperuricemia. Hyperuricemia should be aggressively managed with hydration and antihyperuricemic agents, including allopurinol, in all patients with PMF.

Patients with pre-PMF or low-risk MF, particularly if they are young, are especially challenging for most physicians. These patients are mostly asymptomatic but at risk for evolution to symptomatic MF or acute leukemia. Many patients are eager to entertain options that might prevent disease progression, but presently, an approach that will successfully achieve this goal is not available. HSCT is not an option for these patients due to the inherent morbidity and mortality associated with this approach.

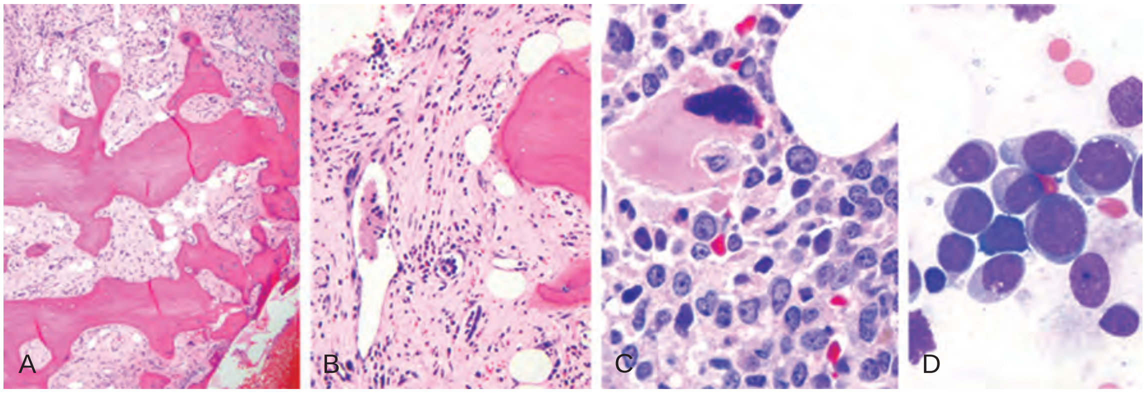

Figure 72.9 DISEASE PROGRESSION IN PRIMARY MYELOFIBROSIS. Marked osteosclerosis (A and B) and acute leukemia (C and D). In some patients, primary myelofibrosis progresses to severe osteosclerosis, in which there is markedly thickened and irregular bone formation (A) and a bone marrow space that is fibrotic and nearly depleted of hematopoietic elements (B). A terminal transformation to acute leukemia (C and D) occurs in 5% to 22% of cases.

TABLE 72.6 **Prognostic Scoring Systems for Primary Myelofibrosis**

Risk Factor	Lille	IPSS	DIPSS	DIPSS Plus	GIPSS	MIPSS70+ v2.0
Anemia (hemoglobin)	X (<10 g/dL)	X (<10 g/dL)	X (<10 g/dL)	X (<10 g/dL)		X (adjusted for sex) Severe (<9 g/dL in males; <8 g/dL in females) Moderate (9–10.9 g/dL in males; 8–9.9 g/dL in females)
Leukocytosis (white blood cell count)	X (<4 or > 30 × 10^9/L)	X (>25 × 10^9/L)	X (>25 × 10^9/L)	X (>25 × 10^9/L)		
Peripheral blood blasts		X (≥1%)	X (≥1%)	X (≥1%)		X (≥2%)
Constitutional symptoms		X	X	X		X
Age (years)		X (>65)	X (adjusted for age)	X		
Karyotype				X (unfavorable[a])	Very high risk[b] Favorable[c] Unfavorable[d]	X
Platelet				X (<100 × 10^9/L)		
Transfusion status				X		
Driver mutations					Absence of type 1-like *CALR*	X
High molecular risk mutations					*ASXL1SRSF2U2AF1*Q157	X

[a] Unfavorable karyotype includes complex or sole or two abnormalities that include +8, −7/7q−, i7/7q−, i(17q), −5/5q−, 12p−, inv (3), or 11q23 rearrangements.

[b] VHR karyotype includes single or multiple abnormalities of −7, i(17q), inv(3)/3q21, 12p−/12p11.2, 11q−/11q23, or other autosomal trisomies not including +8/+9 (eg, +21, +19).

[c] Favorable karyotype includes normal karyotype or sole abnormalities of +9, 13q−, 20q−, chromosome 1 translocation/duplication, or sex chromosome abnormality including −Y.

[d] Unfavorable karyotype includes all other abnormalities.

DIPSS, Dynamic international prognostic scoring system; *IPSS*, international prognostic scoring system; *GIPSS*, genetically inspired prognostic scoring system; *MIPSS 70+ v2.0*, mutation-enhanced international prognostic scoring system plus karyotype, version 2.0.

During the last decade, several investigators have promoted interferon alpha (IFN-α) therapy as an agent that might be capable of delaying disease progression by decreasing the rate of fibrosis if administered chronically during the early course of this disease but not when advanced. In one series, only four of 11 patients were able to complete 1 year of therapy; the other seven patients discontinued the drug because of unacceptable toxicity or severe cytopenias. None of these patients experienced clinically significant improvement (degree of BM fibrosis, osteosclerosis, or angiogenesis). A small phase II pilot study in PMF patients demonstrated responses in patients with pre-PMF treated with low doses of IFN-α-2b over an extended period (median duration: 3 years). Four patients with *JAK2* V617F-positive PMF were followed over time, and although each had clinical responses, only one had a significant reduction in mutant allele burden. The drug was generally well tolerated at doses between 1 and 2 million units weekly, and responses in the BM included a reduction in the degree of reticulin fibrosis and abnormal cellular morphology. Among the eleven PMF patients treated with a pegylated form of IFN-α-2b (PEG-IFN-α-2b; starting doses were between 2 and 3 μg/kg/week), only a single patient responded. Although the pegylated formulation allows for weekly injections, the toxicity profile was similar to the standard formulation and

TABLE 72.7 **Median Survival of Each Risk Group in Six Prognostic Scoring Systems for Primary Myelofibrosis**

Risk Group	Lille (Months)	IPSS (Months)	DIPSS	DIPSS Plus (Months)	GIPSS (Months)	MIPSS70+ v2.0
Low	93	135 s	Not reached	185	367	Very low—not reached
						Low—124 months
Intermediate-1	26	95	170 months	78	95	83 months
Intermediate-2		48	48 months	35	50	
High	13	27	18 months	16	24	42 months

hence limited the duration of therapy in many patients. The most common grade 3/4 toxicity was fatigue and thrombocytopenia. Encouraging results of PEG-IFN-α-2a (Pegasys) in PV patients prompted the evaluation of IFN-α in MF patients. The French Groupe d'Etudes des Myelofibrosis (GEM) and France Intergroupe des Syndromes Myeloproliferatifs conducted a study of 18 patients with PMF and post-ET/PV MF treated with Pegasys. Of the four PMF patients included in this study, one had a complete response, two had a minor response, and one had no response. Responses included improvement in the degree of anemia, leukocytosis, and thrombocytosis but not splenomegaly, and appeared to be irrespective of *JAK2* mutational status. A comprehensive literature review suggests that IFN-α therapy in PMF may be of only moderate benefit in those with advanced phases of the disease. Prospective randomized studies are warranted in patients with pre-MF to determine the effects of IFN-α on disease-free survival, LFS, OS, and QoL. Without systematic evaluation, IFN therapy in any phase of PMF should be considered experimental and not embarked upon unless the patient is participating in a clinical trial.[11]

TREATMENT OF THE ANEMIC PATIENT

Anemia is common in patients with PMF and usually multifactorial in origin; nutrional deficiency (iron, folate), ineffective erythropoiesis, impaired erythroid differentiation, erythroid hypoplasia, increased splenic clearance, and hemolysis. Patients with documented nutritional deficiencies should receive folate, iron supplementation, or both. Packed RBC transfusion is indicated in patients with symptomatic anemia, and hemoglobin levels should be maintained at a level that provides symptomatic relief. Long-term transfusion therapy potentially may lead to iron-overload syndrome. It remains unclear if iron chelation is of meaningful clinical benefit to patients with MF, and data is mostly extrapolated from the MDS literature and anecdotal reports. Low-dose dexamethasone may be useful in patients with transfusion-dependent PMF.

Corticosteroids (e.g., prednisone 1 mg/kg/day taken orally) have been successfully used to treat hemolytic anemia associated with PMF. Other therapeutic options in this setting include intravenous immunoglobulins and recombinant human erythropoietin-α (rEPO). In a retrospective analysis of prednisone monotherapy (0.5 to 1 mg/kg daily, with tapering to the minimum effective dose in responders) in patients with intermediate-2 or high-risk PMF ($n = 30$) and anemia/thrombocytopenia, 12 patients (40%) achieved an anemia response by IWG-MRT criteria. The median response duration was 12.3 months. Patients with constitutional symptoms or greater than 2% circulating blasts had a lower response rate. Median survival from the initiation of prednisone therapy was significantly longer in anemia responders (5.0 years vs. 1.5 years, $P = 0.002$). Additional information supporting the use of corticosteroids for the treatment of MF-related anemia is derived from a prospective clinical trial designed to evaluate the safety and efficacy of the immunomodulatory agent, pomalidomide. This study surprisingly revealed that prednisone alone could induce significant responses in unselected MF patients with severe anemia. In this randomized study, the active control arm that included 21 patients consisted of prednisone (30 mg/day during the first 28-day cycle, 15 mg/day in the second cycle, and 15 mg every other day in the third cycle) plus placebo (up to 12 cycles). Overall, four out of 16 (25%) patients assigned to the control arm who completed three cycles of treatment achieved an anemia response according to the IWG-MRT criteria. Three of the four responses were short-lived, lasting between 2.3 and 5.5 months. This data is similar to our own experience indicating that prednisone therapy can improve PMF-associated anemia and thrombocytopenia even after the failure of standard therapies.

It is important to be aware that hemolytic anemia in patients with PMF may also rarely be a consequence of a coexisting secondary form of paroxysmal nocturnal hemoglobinuria that can be responsive to eculizumab therapy (see Chapter 32). Furthermore, patients with PMF who receive multiple transfusions are at a risk of developing delayed hemolytic transfusion reactions that occasionally may be severe and persistent. The direct antiglobulin test result is usually positive in this setting, and if possible, further transfusions should be limited whenever possible.

Anemia secondary to erythroid hypoplasia or ineffective erythropoiesis in PMF may respond to anabolic steroids. A good response is defined as a decrease, or total avoidance of transfusion therapy, occurring in about 20% to 40% of patients. A course of 3 to 6 months of androgen therapy is indicated to identify responsive patients, but the development of hepatic dysfunction or virilizing side effects may limit long-term androgen administration. Patients with CGAs are less likely to respond to androgen therapy. Danazol, a synthetic attenuated androgen, is useful in reducing RBC transfusion requirements and correcting thrombocytopenia in 20% to 40% of treated patients, in several series. Variables associated with response were a lack of a transfusion requirement and higher hemoglobin levels.

The use of rEPO in PMF was reviewed by Cervantes and colleagues in a total of 51 patients, documenting that 28 (55%) of these patients responded to rEPO treatment, including 16 complete and 12 partial responses. Inappropriately low endogenous serum EPO levels for the degree of anemia are predictive of a favorable response to rEPO. Serum EPO levels below 125 U/L were found to be associated with a favorable response to rEPO therapy. Responses can be associated with a limited enlargement of the spleen. The use of darbepoetin, a hyperglycosylated erythropoiesis-stimulating protein, has been reported in 20 PMF patients. With an initial weekly dose of 150 µg, increased to 300 µg after 4 to 8 weeks if there was a lack of response, eight patients (40%) responded with six complete and two partial responses, and five maintained their response after a median follow-up of 12 months (range: 4 to 22 months). The median time to response was 2 months. Univariate analysis indicated that older age was the only factor associated with a favorable response to treatment ($P < 0.006$). None of the patients with elevated serum EPO levels responded. Treatment was well tolerated, and patients could be successfully switched from rEPO to darbepoetin.

Multiple trials have explored the use of thalidomide in the treatment of anemia in PMF based on the drug's antiangiogenic, immunomodulatory, and antiinflammatory properties. A pooled analysis of five small phase II studies indicated that 29% of patients with moderate to severe anemia experience an increase in hemoglobin or reduction or elimination of blood transfusion requirements with thalidomide therapy at a standard dose of 200 to 800 mg/day. Nevertheless, most of the patients treated with these doses suffered adverse effects that resulted in an attrition rate of greater than 50% after 3 months. Moreover, an increase in white blood cell or platelet counts was frequently associated with serious adverse events such as pericardial effusions secondary to myeloid metaplasia. In a dose-escalation study design, at a low starting dose of thalidomide (50 mg/day), 31% of patients with transfusion-dependent anemia responded to therapy. A combination of low-dose thalidomide (50 mg/day) with prednisone was better-tolerated and equally or more effective than the standard-dose regimen. This regimen also had a significant effect on the degree of thrombocytopenia and resulted in a modest reduction of splenomegaly in almost 10% of the patients. These responses were sustained even after cessation of therapy. Higher doses of thalidomide were not more effective than lower doses. In a prospective phase IIB, randomized, double-blind, multicenter trial that compared 200 to 400 mg of thalidomide with placebo, only 10 out of 26 patients in the thalidomide arm completed 6 months of treatment. No difference was observed between the thalidomide and placebo arms in regard to the improvement of hemoglobin levels or decrease in RBC transfusion requirement. In a two-stage, phase II dose-escalation trial of thalidomide (200 mg dose-escalated to 800 mg as tolerated) in 44 patients with advanced PMF, the median tolerated dose was 400 mg for a median duration of 3 months, and 20% of the patients experienced an improvement in their degree of anemia (21% became transfusion-independent).

A more potent thalidomide analog, lenalidomide, was evaluated in 68 symptomatic patients with PMF at two institutions. Oral lenalidomide was administered at a dose of 10 mg/day if the platelet count was greater than 100,000/mm^3 or at a dose of 5 mg/day if the platelet count was less than 100,000/mm^3 for 3 to 4 months. The overall response rates were 22% for patients with anemia, 33% for patients with splenomegaly, and 50% for thrombocytopenia. Several patients normalized their hemoglobin levels or became RBC transfusion independent. The most common associated toxicities were grade 3 and 4 neutropenia and thrombocytopenia, which occurred in approximately 30% of patients but resolved with therapy cessation. In several patients with del(5)(q31)-associated PMF or post-PV MF, lenalidomide therapy was associated with a cytogenetic response as determined by FISH and a reduction in *JAK2* V617F VAF. Lenalidomide and prednisone combination therapy in PMF was evaluated in a phase II trial within the Eastern Cooperative Oncology Group and appeared to be modestly active but myelosuppressive. 42 MF patients with anemia were treated with lenalidomide at 10 mg/day in combination with a 3-month prednisone taper. Grade 3 or higher myelotoxicity was noted in 88% of patients, with an IWG-MRT response rate of 23% (19% clinical improvement in anemia or 10% clinical improvement in spleen size). Whether either of these immunomodulatory drugs (IMiDs) is superior to the other is a subject of speculation that could only be answered by a large randomized clinical trial.

Because IMiDs as a class have shown activity in MF and their use is often undermined by neurotoxicity or myelosuppression, recent interest in the structurally related but more potent pomalidomide in the treatment of MF-associated anemia has led to the completion of several early-phase studies and a randomized phase III study. The first study to evaluate the response of pomalidomide in MF was a phase II randomized, double-blind, placebo-controlled adaptive design study with four treatment arms. This study reported an overall response in anemia of 24% (10 patients), and 15 of these patients achieved transfusion independence that was durable at 7.5 months. Pomalidomide at 0.5 mg/day with or without a prednisone taper was found to have better anemia responses with less toxicity compared with pomalidomide at 2 mg/day with or without prednisone. Grade 3/4 myelosuppression and neurotoxicity were not frequent adverse events. A single-center phase II study of low-dose pomalidomide was conducted at Mayo Clinic. A cohort of 58 patients was treated with pomalidomide at 0.5 mg/day. Of the 42 transfusion-dependent MF patients, ten had significant anemia responses, with nine patients achieving transfusion independence. Although there were no spleen responses, a 58% response in thrombocytopenia for those with baseline platelets below 100 × 10^9 cells/L was noted. Anemia response was predicted by peripheral blood basophilia within the first month of therapy and the absence of massive splenomegaly and was restricted to *JAK2* V617F-mutated PMF patients. Pomalidomide was also evaluated in phase I/II dose-escalation setting to determine if higher doses of pomalidomide were more effective in reversing the anemia associated with MF. The maximum tolerated dose (MTD) was 3 mg/day given for 21 out of 28 consecutive days, and myelosuppression was the dose-limiting toxicity without any added effects on the number of anemia responses. The placebo-controlled, randomized, phase III RESUME trial compared pomalidomide at 0.5 mg/day with placebo with an opportunity to crossover and enrolled both *JAK2*-mutated and wild-type MF patients with documented anemia. The primary endpoint of anemia response was not met in this large global trial as both arms achieved TI in 16% of treated patients. However, 21% of patients achieved clinical improvement in platelet count with pomalidomide therapy compared to none of the placebo-treated patients. Whether this trial would have had positive results if eligibility had been restricted to MF patients with *JAK2* V617F and limited splenomegaly remains conjecture.

TGF-β facilitates aberrant signaling of stromal cells in the bone marrow microenvironment of MF, resulting in erythroid maturation arrest during erythropoiesis. The activin receptor TGF-β family ligand traps, sotatercept and luspatercept, administered subcutaneously every 3 weeks, prevent ligand binding to activin receptors IIA (sotatercept) and IIB (luspatercept), reduce aberrant SMAD signaling, and promote terminal erythroid differentiation. In a phase II study of sotatercept monotherapy and in combination with ruxolitinib, in 20 evaluable MF patients with anemia, 35% of patients responded to sotatercept monotherapy, of which three patients achieved RBC-transfusion independence (TI); 23% of TI patients experienced an increase in hemoglobin percentage with ruxolitinib combination therapy (NCT01712308). The recently presented study of luspatercept monotherapy and combination therapy with ruxolitinib evaluated TI ($n = 34$) and TD ($n = 40$) patients with MF. Among the TI patients, 10% in the monotherapy arm and 21% in the combination arm achieved a sustained hemoglobin increase ≥1.5 g/dL at ≥12 weeks. Among the TD patients, 10% in the monotherapy arm and 32% in the combination arm achieved RBC-TI for ≥12 consecutive weeks (NCT03194542). Sotatarcept and luspatercept were reasonably well tolerated and shared class-specific treatment-emergent adverse events (TEAEs), that is, hypertension and bone pain. Further evaluation of luspatercept is ongoing, both as a single agent and in combination with ruxolitinib in MF patients with anemia.

TREATMENT OF SPLEEN-RELATED AND SYSTEMIC SYMPTOMS

Historically, pressure symptoms related to splenomegaly have been treated with cytotoxic chemotherapy, namely busulfan, melphalan, and hydroxyurea. Occasionally, a significant reduction in spleen size with symptom alleviation occurs in patients receiving chemotherapy. Unfortunately, these responses are short-lived, lasting a median of only 4.5 months. Only 16% of patients enjoy sustained relief of symptoms on long-term maintenance therapy. Accompanying hematologic toxicity often necessitates curtailing therapy within a short duration. This evident lack of effective treatment options in PMF led to the development of oral small-molecule tyrosine kinase inhibitors targeting the hyperactive JAK-STAT signaling pathway.

Ruxolitinib, a selective JAK1 and JAK2 tyrosine kinase inhibitor, was the first drug to be approved by the United States Food and Drug

Administration (US FDA) in 2011 for the treatment of patients with intermediate- or high-risk MF. The phase I/II study determined 15 mg twice daily as the optimal starting dose, with thrombocytopenia and worsening anemia as dose-limiting toxicities. Dose-dependent suppression of phospho-STAT3 was observed in both *JAK2*-mutated and nonmutated patients treated with ruxolitinib, thus demonstrating ruxolitinib's inhibitory activity regardless of the *JAK2* mutational status. 52% of treated patients achieved a greater than 50% reduction in splenomegaly for more than 12 months, irrespective of their *JAK2* mutational status. The debilitating symptoms associated with MF dramatically improved, which correlated with a decrease in inflammatory cytokines mediated through inhibition of JAK1 signaling. Ruxolitinib was then evaluated in two randomized phase III trials: COMFORT 1 (United States, Canada, and Australia), in which ruxolitinib therapy was compared with placebo, and COMFORT 2 trial (Europe), in which ruxolitinib was compared with the best available therapy.[12,13] The results of each of these trials are remarkably similar, and each trial was adequately powered. Patients with intermediate-2 or high-risk MF as assessed using the IPSS were eligible regardless of *JAK2* mutational status. All patients had platelet counts over 100 × 10^9/L with a palpable spleen at least 5 cm below the left costal margin.

In COMFORT 1, the primary endpoint, 35% or greater splenic volume reduction (SVR) was met at 24 weeks in 41.9% of the ruxolitinib-treated cohort and only 0.7% in the placebo group. This response was maintained for 48 weeks or more in 67% of treated patients. Fig. 72.10 shows the percent change in spleen volume from baseline at week 24 for individual patients on both arms of this trial, which depicts the striking contrast of spleen reduction in ruxolitinib-treated patients compared with the majority of patients in the placebo arm who had an increase in spleen volume. There were 13 deaths in the ruxolitinib arm and 24 deaths in the placebo arm, revealing a modest survival benefit for MF patients treated with ruxolitinib. Although grade 3/4 anemia and thrombocytopenia were frequent in the ruxolitinib arm (45.2% and 12.9%, respectively), discontinuation for these events was extremely rare.

The primary endpoint in the COMFORT-2 trial was met at 48 weeks, with 28% of patients in the ruxolitinib arm and 0% in the BAT arm achieving at least a 35% SVR. The mean length of palpable spleen decreased by 56% at 48 weeks, compared with an increase of 4% in the BAT arm. Sophisticated disease-specific QoL tools were used to evaluate the effects of ruxolitinib therapy on systemic symptoms secondary to the elaboration of inflammatory cytokines modulated by JAK1 signaling. The effects of ruxolitinib were, however, limited in the reversal of histomorphologic abnormalities, including BM fibrosis or osteosclerosis, a significant reduction in the *JAK2* V617F allele burden, and loss of marker CGAs, which indicates that it does not modify the underlying neoplastic potential of PMF. Abrupt cessation of ruxolitinib therapy can lead to "ruxolitinib withdrawal syndrome" characterized by rapid onset splenomegaly, worsening of cytopenias, acute relapse of disease symptoms, and occasional hemodynamic and pulmonary decompensation, which may at times be fatal. Gradual tapering and/or the use of a short steroid taper is recommended to avoid this complication.

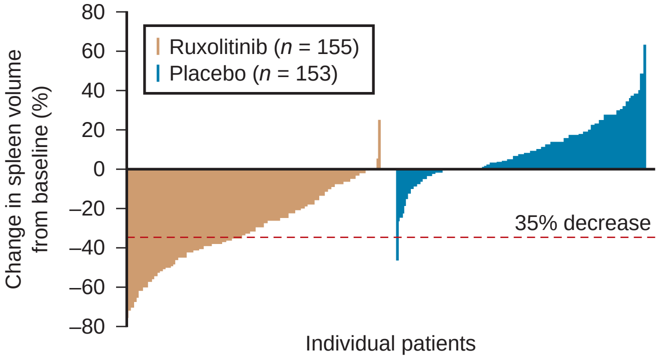

Figure 72.10 REDUCTION IN SPLENIC VOLUME WITH RUXOLITINIB THERAPY IN THE COMFORT I TRIAL. The waterfall plot shows the percent change from baseline in spleen volume at week 24 (in 139 patients in the ruxolitinib group and 106 in the placebo group) or at the last evaluation before week 24 (in 16 patients in the ruxolitinib group and 47 in the placebo group). Data for one patient with a missing baseline value are not included on the graph. Most patients in the ruxolitinib group (150 out of 155) had a reduction in spleen volume, but most patients in the placebo group had either an increase in spleen volume (102 out of 153 patients) or no change (15 out of 153 patients). *(From Verstovsek S, Mesa RA, Gotlib J, et al. A double-blind, placebo-controlled trial of ruxolitinib for myelofibrosis. N Engl J Med. 2012;366:799.)*

Ruxolitinib is an important agent for the palliation of symptomatic splenomegaly and the debilitating symptoms seen in patients with PMF. The favorable survival data from the COMFORT 1 trial, although modest, are intriguing and suggest that even if a considerable impact on abnormal BM histopathology or molecular or cytogenetic responses is not seen with ruxolitinib, pharmacologic suppression of the JAK-STAT pathway decreases the risk of death, perhaps simply by improving the overall performance status, and reversing the cancer cachexia of an individual. Ruxolitinib has been demonstrated to be safe in patients with a minimum platelet count of 50 × 10^9/L. The need to treat patients who are asymptomatic with limited splenomegaly is not apparent as the treatment does not modify the disease course. The most recent planned analysis of COMFORT-1 at 5 years demonstrated a durable response in spleen reduction and symptom improvement in those subjects who remained on ruxolitinib. No new/unexpected toxicities or late-onset emergent hematologic adverse events were reported. However, it should be noted that a 50% discontinuation rate at 3 years was reported in the arm randomized initially to ruxolitinib, and the potential for leukemic transformation with extramedullary involvement has also been reported.

Patients treated with ruxolitinib are at an increased risk for infectious complications, including reactivation of latent herpes zoster infections leading to shingles, toxoplasmosis, cryptococcal pneumonia, reactivation of latent herpes simplex virus and hepatitis B, and disseminated tuberculosis. Ruxolitinib affects components of both innate and adaptive immunity, including natural killer cells, dendritic cells, and T cells (Th and Tregs). A concern was raised regarding an association between ruxolitinib exposure and the risk of aggressive C-MYC-driven lymphoproliferative neoplasms in these patients. However, several retrospective studies have failed to show an association between the development of lymphoma and ruxolitinib exposure. Importantly, the clinical consequences of ruxolitinib therapy in patients with preexisting B-cell clones warrant further prospective studies.

Following the approval of ruxolitinib in 2011, FDA approval of the selective JAK2 inhibitor fedratinib in August 2019 provided an alternative JAK2 inhibitor for the treatment of patients with intermediate-2 or high-risk PMF with a baseline platelet count ≥50,000/mm^3 irrespective of prior JAK inhibitor treatment. JAKARTA, a randomized, multicenter, double-blind, placebo-controlled phase III trial, evaluated the safety and efficacy of fedratinib in patients with PMF.[14] Patients were evaluated in three arms: fedratinib 400 or 500 mg daily, or placebo for 24 weeks with crossover from placebo after that time. The primary endpoint was ≥35% SVR at 24 weeks. The secondary endpoint was a 50% reduction in symptom burden indicated by the Myelofibrosis Symptom Assessment Form (MFSAF). Among the 289 enrolled patients (96 at 400 mg of fedratinib, 97 at 500 mg of fedratinib, and 96-placebo), 36% and 40% of patients in the fedratinib 400-mg and 500-mg arms, respectively, achieved spleen response as opposed to 1% in the placebo arm ($P < 0.001$). MFSAF score reduction was achieved in 36% and 34%, in those who received 400 mg and 500 mg of fedratinib, respectively, as opposed to 7% in the placebo arm. No appreciable changes in the *JAK2*V617F VAF were observed. The drug was generally well tolerated and anemia was the most common hematological TEAE. Nonhematological TEAE include gastrointestinal toxicities, predominantly low-grade nausea, and diarrhea in the first month that diminished over time. Of note, four patients in the 500 mg fedratinib arm experienced Wernicke encephalopathy, which led to an abrupt FDA-mandated clinical hold and closure of the JAKARTA study in 2013.

JAKARTA-2, conducted in parallel with the JAKARTA study, was an open-label, phase II study that evaluated the safety and efficacy of fedratinib in 97 patients with intermediate-1-high-risk MF who were deemed intolerant or resistant to ruxolitinib by the investigator.[15] A precise definition of ruxolitinib intolerance or resistance was not described at that time. Dose escalation up to 600 mg from 400 mg was permitted if there was less than 50% reduction in palpable spleen size by the end of cycles 2 and 4. This study was also halted early due to the FDA clinical hold. A recent reappraisal of the JAKARTA-2 study data reported that a 31% SVR and 27% symptom response at 24 weeks in the intention to treat cohort was observed. The hematologic and nonhematologic TEAEs were as reported previously. Unfortunately, long-term follow-up data are not available due to the early cessation of the study.

The path to FDA approval of fedratinib was challenging due to the clinical hold placed between 2013 and 2017. An independent central review determined that among the original eight reported potential cases of Wernicke encephalopathy, there was only one definitive confirmed case of Wernicke encephalopathy (clinical and confirmatory MRI). This led to the FDA black box warning of the risk of serious and fatal encephalopathy, including Wernicke encephalopathy. These concerns have resulted in prophylactic oral thiamine administration routinely in patients being treated with fedratinib. The ongoing postmarketing phase III/IIIb FREEDOM studies (NCT03755518, NCT03952039) will add to the overall safety data of fedratinib. Given that both ruxolitinib and fedratinib are only approved for the treatment of patients with MF with a baseline platelet count ≥50,000/mm^3, there is an urgent unmet need for effective treatment options in MF patients with anemia and thrombocytopenia. Momelotinib (JAK1/JAK2 inhibitor) and pacritinib (JAK2/FLT3 inhibitor) are currently being evaluated in phase III registration trials and have the potential to be used as either first-line agents in ruxolitinib-naïve patients with significant baseline cytopenias, or as second-line agents for patients experiencing ruxolitinib-associated cytopenias or loss of clinical response.

Momelotinib, in addition to the JAK1/2 inhibition, was also shown to inhibit bone morphogenic protein receptor kinase activin A receptor type I (ACVR1)–mediated hepatocyte hepcidin expression, which has been shown to stimulate erythropoiesis in murine models of chronic anemia. This suppression of hepcidin was thought to lead to increased mobilization of sequestered iron from cellular stores and subsequent stimulation of erythropoiesis. In the phase III SIMPLIFY-1 study of momelotinib versus ruxolitinib in treatment naïve patients with intermediate- or high-risk MF, momelotinib achieved its prespecified primary endpoint (SVR 35%) of noninferiority to ruxolitinib (momelotinib: 26.5%; ruxolitinib: 29.0%; 95% CI: −11.2% to +5.6%; $P = 0.011$). However, the key secondary endpoint, TSS50, did not meet the noninferiority, therefore formal sequential statistical testing was not undertaken for the three additional anemia secondary endpoints [proportion of patients who are TI, TD, or transfusion rate]. About 66.5% of patients treated with momelotinib achieved TI compared with those treated with ruxolitinib (49.3%; nominal $P < 0.001$). In the phase III SIMPLIFY-2 study of momelotinib versus BAT in patients with intermediate- or high-risk MF with prior JAK inhibitor exposure, momelotinib did not achieve its primary endpoint (only 7% in the momelotinib group and 6% in the BAT group attained SVR 35%; 95% CI –0.09 to 0.10; $P = 0.90$). However, in secondary endpoint analyses, 43% of patients in the momelotinib arm were TI at week 24 compared to 21% patients in the BAT arm ($P = 0.0012$), and 40% of momelotinib-treated patients did not require transfusions over the treatment phase, compared with 27% of patients in the BAT group (nominal $P = 0.10$). The effects of momelotinib on stimulating erythropoiesis, inducing anemia responses, and achieving transfusion independence suggest that this drug may particularly benefit patients with MF-associated anemia. Therefore MOMENTUM, a randomized, double-blind global phase III trial, will evaluate the efficacy of momelotinib compared to danazol in patients with MF and anemia after previous treatment with ruxolitinib (NCT04173494).

Pacritinib is a JAK2/FLT3/IRAK1 inhibitor with substantial early clinical development data indicating efficacy and minimal myelosuppression in MF. The phase III multicenter randomized, controlled, PERSIST-1 trial evaluated pacritinib in a JAK inhibitor-naïve population ($n = 327$), and met its primary endpoint of SVR35% (19% with pacritinib compared to 5% with BAT) at week 24. The phase III PERSIST-2 trial was conducted in thrombocytopenic patients (baseline platelet count $\leq 100 \times 10^9$/L) not excluding prior ruxolitinib exposure and compared two doses of pacritinib (400 mg once daily, the dose evaluated in PERSIST-1, and 200 mg twice daily) to BAT. Although 311 patients were recruited, only 221 (75, 74, and 72 in the three arms) could be included in the ITT efficacy population as trial accrual was affected by the imposition of a "full clinical hold" on pacritinib development by the FDA in February 2016 due to concern over high-grade cardiac and hemorrhagic events leading to increased mortality risk in the PERSIST studies. This ultimately led to the dose-finding PAC 203 trial in MF patients with ruxolitinib failure and a platelet count $<100 \times 10^9$/L (200 mg BID; 100 mg QD; and 100 mg BID). Greatest SVR35% rate (17%) and improvement in symptom scores were observed with 200 mg twice daily of pacritinib. Of note, SVR benefit was seen in subgroups of patients with thrombocytopenia in the PERSIST-1, PERSIST-2, and PAC 203 studies, suggesting that pacritinib may be a reasonable therapeutic option in patients with MF and baseline severe thrombocytopenia. The phase III PACIFICA study will compare pacritinib to Physician's Choice therapy for patients with MF and severe thrombocytopenia (platelet counts <50,000/μL) with less than 3 months of prior ruxolitinib exposure (NCT03165734).

Splenic irradiation was frequently used in the past for treatment of the painful large-spleen syndrome but is now considered a last-resort option with the approval of JAK1/2 inhibitor therapy. Radiation in fractions of 0.15 to 1 Gy administered daily or by an intermittent fractionation schedule (i.e., two or three times a week) to a total dose per treatment course of 2.5 to 6.5 Gy may be effective. Responses were transient, lasting an average of 3.5 months, and hematopoietic toxicity was frequently significant. Splenic irradiation is still useful for the treatment of splenic pain of sudden onset and treatment of ascites caused by implants of hematopoietic tissue. Radiation therapy should be considered as a temporary measure to be used in patients who are too ill to tolerate splenectomy or chemotherapy. Splenic irradiation is limited by myelosuppression and prolonged cytopenias, which is neither predictable nor does it correlate with the radiation dose.

Radiotherapy offers a viable treatment option and sometimes maybe the therapy of choice for patients with symptomatic hepatomegaly, peritoneal and pleural implants or pulmonary infiltration leading to ascites or pleural effusions, and EMH in vital organs leading to organ dysfunction. Given the exquisite sensitivity of myeloid tissue to radiation and profound BM suppression that may occur after irradiation, therapy is usually initiated at low doses (20 to 25 cGy/day) and modified as the clinical situation dictates. An alternative approach using intraperitoneal administration of cytosine arabinoside has been used to treat ascites in PMF. Low-dose, single-fraction, whole-lung radiotherapy has also been useful in treating pulmonary arterial hypertension associated with PMF.

Splenectomy remains a viable option even in the face of recent availability of JAK2 inhibitors in patients with hemolysis, thrombocytopenia, painful splenomegaly, recurrent splenic infarction, and portal hypertension refractory to other therapeutic modalities or in individuals with leukopenia or thrombocytopenia that prevents one from resorting to therapy with chemotherapeutic agents or a JAK2 inhibitor. Splenectomy in patients with PMF is associated with a postoperative morbidity rate of 15% to 30% and a mortality rate of almost 10%. The appropriate implementation of splenectomy can improve QoL in PMF patients who frequently do not have other therapeutic options. Because splenectomy is associated with significant morbidity and mortality, the physician should only resort to this strategy if thrombocytopenia, anemia, or symptomatic splenomegaly is unresponsive to less invasive approaches such as JAK2 inhibitor therapy. Progressive hepatomegaly and marked thrombocytosis occurred in 16% and 22% of patients, respectively, after splenectomy and can often be controlled with JAK inhibitor therapy.

ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

Allogeneic HSCT is a potentially curative therapeutic option in patients with MF and successful transplantation is associated with gradual resolution of BM fibrosis, reduction in splenomegaly, and normalization of hematopoiesis (see box on Algorithm for Selection of Appropriate Patients for Stem Cell Transplantation Stratified According to Risk Status). Historically, allo-HSCT has been recommended for the transplantation of eligible patients with intermediate-2 and high-risk MF. More recently, a 2018 update of European LeukemiaNet (ELN) guidelines also included an intermediate-1 risk score group with refractory transfusion-dependent anemia, having ≥2% blasts, adverse cytogenetics, or high-risk mutations.

Most of our understanding of the role of HSCT in primary and post-PV/ET MF with a conventional myeloablative conditioning (MAC) regimen is derived from two retrospective series of transplants with more than 50 patients performed between 1979 and 2002. The median age of transplanted patients was 42 and 43 years;

treatment-related mortality (TRM) was 27% and 33%, with a 5-year survival of 47% and 58%, respectively. The 5-year probability of treatment failure caused by non-engraftment, relapse, or persistent disease after transplantation was 36%, and the failure of sustained engraftment was 10.7%, which occurred solely in patients receiving BM transplants from mismatched or unrelated donors. The probability of grade III to IV acute graft-versus-host disease (GVHD) was 33% and 21%, and extensive chronic GVHD was 35% and 50%, respectively. Older age and factors associated with more advanced disease (Hg < 10, increased number of RBC transfusions, presence of osteomyelosclerosis, increased number of clonal abnormalities) adversely affected the outcome. The Seattle group updated their 15-year experience with 95 PMF and post-PV/ET MF patients who received MAC with busulfan and/or TBI-containing regimens. The 7-year actual survival rate was 61%, although 10% of patients died of recurrent or persistent disease. NonTBI–containing regimen of targeted busulfan/cytoxan resulted in an improved probability of survival of 68%. These retrospective reports of MAC allo-HCT in PMF provided evidence that engraftment can be achieved, and that a complete and durable remission of the disease can occur in approximately 50% of patients. However, owing to the poor transplant outcomes in older patients, the use of MAC HSCT represents a major therapeutic dilemma in PMF, where patients are primarily diagnosed in their 60s.

The advent of non-MAC, reduced-intensity conditioning (RIC) regimens for aHCT has resulted in decreased TRM and expanded the use of this treatment modality to older patients. The MPD-Research Consortium (MPD-RC) study by Rondelli and coworkers provided one of the initial prospective reports on the outcome of RIC-based transplant (PBSC, matched related or unrelated donor) in 21 intermediate- to high-risk PMF patients (without leukemic transformation) with a median age of 54 years (range: 27 to 68 years). Predominantly fludarabine-based RIC regimens allowed engraftment in all but one patient with a TRM of 10% and 2-year OS rates of 87%. Durable remission was achieved in 17 out of 18 patients alive at 12 to 122 months (median: 31 months) after transplant. Three patients relapsed, with two of them able to achieve remission following a second transplant and donor lymphocyte infusion. Thirty-three percent of patients developed acute GVHD grades II to IV (9% grade III to IV), and 72% developed chronic GVHD.

A CIBMTR retrospective data of 223 patients who underwent RIC fludarabine-based HCT between 1997 and 2010 showed a 47% probability of 5-year survival. Donor type was the only significant factor influencing survival, with 56% vs. 48% vs. 34% 5-year OS in the related donor, matched unrelated donor, and mismatched unrelated donor, respectively. A trend toward decreased mortality was observed in patients with a low/intermediate-1 DIPSS score versus intermediate-2/high-risk DIPSS.

The use of RIC PBSC transplantation in patients with advanced MF was evaluated prospectively in two phase II trials by the European Group for Blood and Marrow Transplantation (EBMT) and MPD-RC. The EBMT trial included 103 MF patients transplanted from related ($n = 33$) or unrelated donors ($n = 70$), with 21% of donors having at least one allele or antigen mismatch using a fludarabine/busulfan/ATG regimen. Although all but two patients achieved initial engraftment, secondary graft failure (GF) or poor graft function (PGF) occurred in 11% of patients. The estimated 5-year EFS and OS were 51% and 67%, respectively. One-year nonrelapse mortality was 16%—similar among related and unrelated donor transplants but significantly higher in mismatched transplants (38% vs. 12%). One-third of patients developed grade II-IV acute GVHD (11% grade III to IV), with half of the patients affected by chronic GVHD (24% extensive). Relapse rate/treatment failure at 3 and 5 years was 22% and 29%, respectively. As can be seen in Fig. 72.11, age over 55 years, human leukocyte antigen (HLA) mismatching, and advanced disease are associated with decreased PFS and OS. However, even in this high-risk group, the OS was approximately 40%. Remarkably, patients younger than 55 years of age had a 5-year OS rate of 82%. Elimination of *JAK2* V617F after transplant was associated with a reduced incidence of relapse.

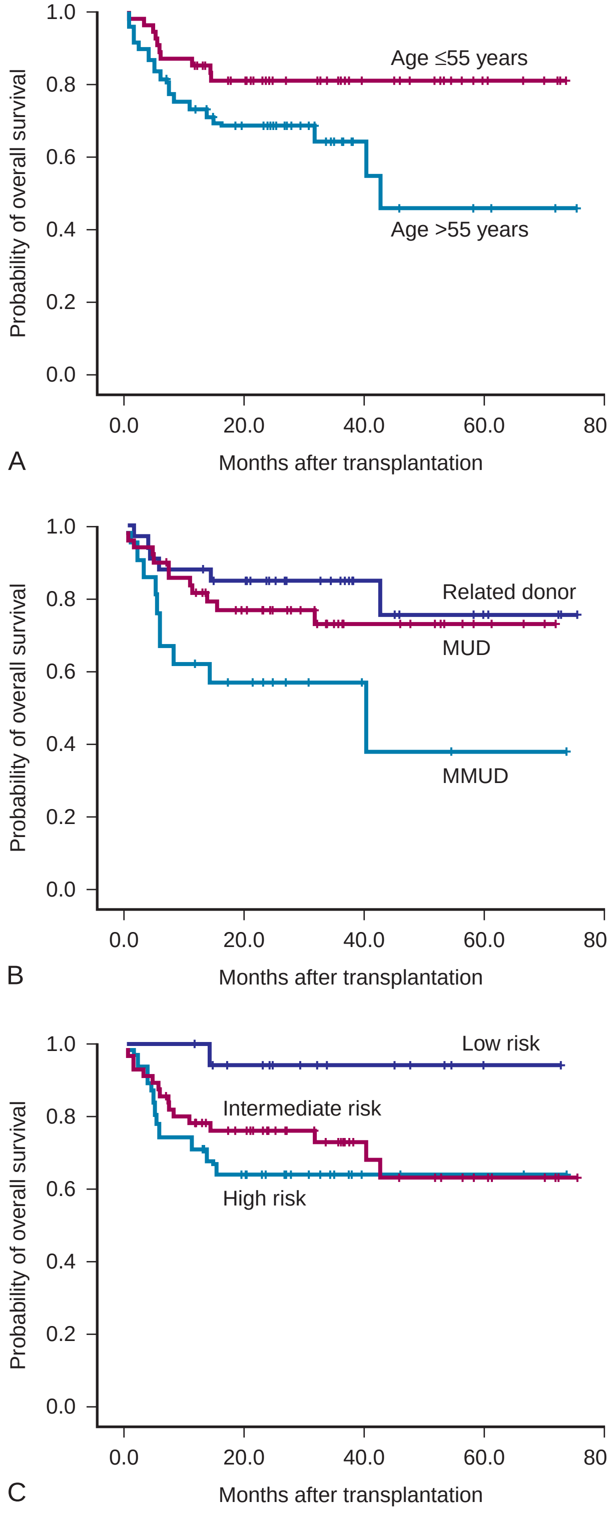

Figure 72.11 Survival of patients with myelofibrosis after reduced-intensity allogeneic stem cell transplantation according to age (A), donor (B), and Lille risk profile (C). *MMUD*, Mismatched unrelated donor; *MUD*, matched unrelated donor.

The prospective, multicenter phase II MPD-RC 101 trial included two parallel cohorts of patients: related donors ($n = 32$, 94% HLA matched) and unrelated donors ($n = 34$, 74% HLA matched). Fludarabine/melphalan was used as a conditioning regimen with rabbit antithymocyte globulin (rATG) added to the unrelated donor group. Patient characteristics were similar in the two groups, with 63 out of 66 patients having intermediate- to high-risk disease based on the Lille score. After a median of 25 months follow-up, OS was 75% (median not reached) in the related donor cohort and 32% (median:

6 months) in the unrelated donor. Nonrelapse mortality at 59% was significantly higher in the unrelated group compared with 22% in the related group. GF occurred in 36% (24% primary) of unrelated transplants and 6% (3% primary) of related. The unrelated cohort had double the rate of severe acute GVHD grade III to IV (21% vs. 12%) but comparable rates of chronic GVHD (38% vs. 36%), including extensive form (20% vs. 25%). Patients who were able to achieve sustained stem cell engraftment experienced an overall response rate of 93% in the related group and 69% in the unrelated group, with only four patients suffering progression of disease. Neither the diagnosis (primary or secondary MF), HLA mismatch, presence of *JAK2* V617F mutation, nor age greater than 57 years showed a statistically significant effect on survival. The only factor that correlated with improved survival was related donor type, as seen in Fig. 72.12. The low/intermediate-1–risk patients in the unrelated group had better survival than the intermediate-2/high-risk patients, whereas there was no difference in survival between these two DIPSS groups in the related group.

The German group analyzed the effect of multiple risk factors related to the patient, disease, and transplant characteristics on survival after RIC HCT and developed a predictive model based on three risk factors: age ≥57 years, *JAK2* WT status, and presence of constitutional symptoms. Five-year OS in the absence of any risk factors was 90%. The presence of one or two risk factors reduced 5-year OS to 74% and 51%, respectively. Patients who had all three risk factors did extremely poorly after RIC HCT, with a 1-year OS of 25%. Despite inferior outcomes in older patients, HCT is feasible, as demonstrated by a retrospective study of HCT of 30 PMF patients between the ages of 60 and 78 (median: 65) years transplanted at four major US academic centers with 3-year OS and PFS rates of 45% and 40%, respectively.

More recently, Gagelmann et al. utilized clinical variables including transplant related (age ≥57 years, Karnofsky performance status <90%, platelet count <150 × 10^9/L, leukocyte count >25 × 10^9/L, HLA-mismatched unrelated donor) and molecular variables (presence of *ASXL1* mutation, and a non-*CALR*/*MPL* genotype) to develop an integrated model (Myelofibrosis Transplant Scoring System [MTSS]) to specifically predict the outcomes of HSCT in MF. In the multivariable analysis of 361 patients with MF (both primary and secondary to PV/ET) who underwent their first HSCT, HR weighted risk points were allotted 2 points each to HLA-mismatch unrelated donor and non-*CALR*/*MPL* genotype; 1 point each to age ≥57 years,

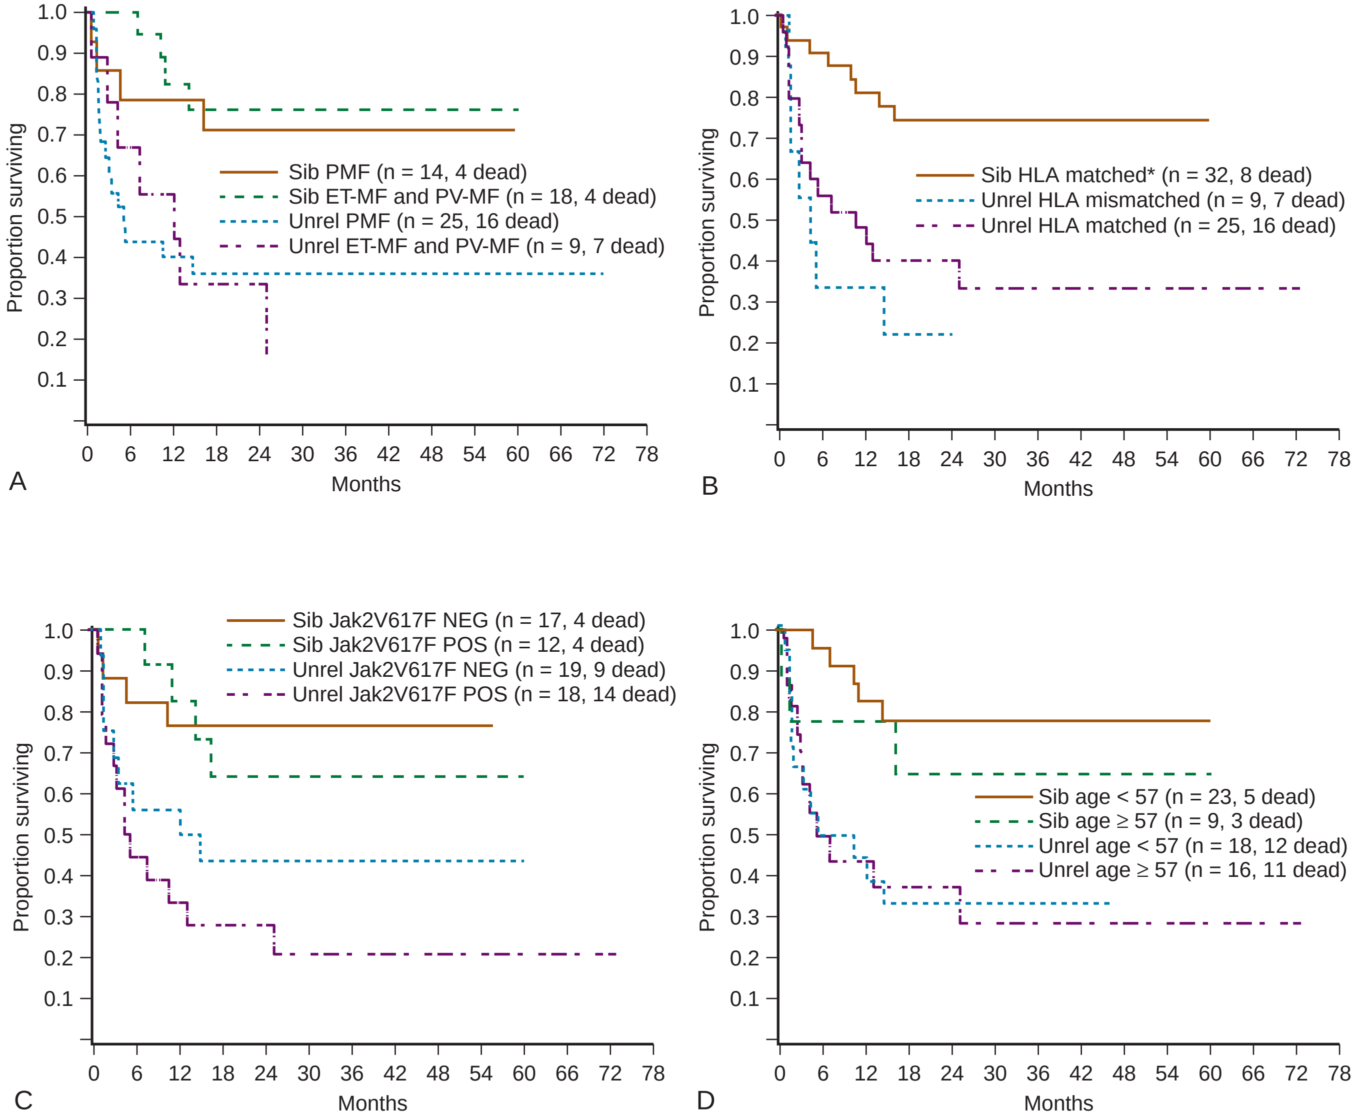

Figure 72.12 Survival for patients with myelofibrosis after receiving reduced-intensity allogeneic stem cell transplantation was worse in the unrelated donor cohort, compared with the related donor cohort irrespective of (A) diagnosis subtype, (B) degree of HLA matching, (C) *JAK2* mutational status, and (D) age. Final results from the multicenter phase II MPD-RC 101 trial. *ET-MF*, Essential thrombocythemia myelofibrosis; *HLA*, human leukocyte antigen; *NEG*, negative; *PMF*, primary myelofibrosis; *POS*, positive; *PV-MF*, polycythemia vera myelofibrosis. *(Data from Rondelli D, Goldberg JD, Isola L, et al. MPD-RC 101 prospective study of reduced-intensity allogeneic hematopoietic stem cell transplantation in patients with myelofibrosis. Blood. 2014;124:1183.)*

Karnofsky performance status less than 90%, platelet count less than 150×10^9/L, leukocyte count greater than 25×10^9/L, and presence of the *ASXL1* mutation. This resulted in a 4-tiered risk predictive model: low (0 to 2 points), intermediate (3 to 4 points), high (5 points), and very high (>5 points) with 5-year OS posttransplant of 83%, 64%, 37%, and 22%, respectively ($P < 0.001$). The MTSS performed exceedingly well compared to similar models (MIPSS70 or the MYSEC-PM) validated in a nontransplant setting.

Wider access to allogeneic HSCT for MF patients has been limited by the availability of HLA-matched donors. Over the past two decades, use of alternative donors such as umbilical cord blood (UCB) and related half-HLA-matched (haploidentical) donors has greatly expanded the donor pool (see Chapters 106, 107, and 108). Takagi and coworkers reported encouraging results of RIC-HCT with UCB grafts in adults (median age, 57.5 years) with various hematologic disorders associated with extensive bone marrow fibrosis. The estimated probability of survival at 4 years was 28.6%, which is modest but considerably superior to that which would be anticipated with currently available therapeutic regimens for such high-risk patients. A retrospective analysis of 35 high-risk MF patients (20% MPN-BP, median age: 54) who underwent UCB transplantation reported by Eurocord showed a 2-year OS and EFS of 44% and 30%, respectively.

An Italian group reported a retrospective analysis of 95 patients demonstrating improvement in HSCT outcomes for patients transplanted between 2011 and 2014 when predominantly using siblings and haploidentical donors (see Chapter 107) with myeloablative thiotepa/busulfan/fludarabine (TBF) conditioning, as compared to patients transplanted between 2000 and 2010 ($n = 58$) using predominantly siblings and unrelated donors and RIC. Bone marrow was the predominant source of stem cells in both groups. Factors leading to improvement in transplant outcomes were attributed to the general improvement in posttransplant care over time (as demonstrated by improved outcomes of the matched-related transplants), TBF conditioning, as well as the use of haploidentical rather than unrelated donors. Retrospective analysis by EBMT society of 56 patients with MF who underwent haploidentical transplant (see Chapter 107) confirmed favorable outcomes with low rates of acute and chronic GVHD, comparable rates of GF, and relapse to matched donors. These studies provide the rationale for the further evaluation of RIC allogeneic transplants for eligible PMF patients lacking an HLA-matched sibling or unrelated donor with the use of alternative sources of grafts such as UCB and haploidentical donors.

Despite the curative nature of HSCT in the treatment of MF, up to 30% of patients experience relapse of their disease. Elimination of *JAK2*V617F after transplant was associated with a reduced risk of relapse, while persistence of known molecular markers (*JAK2, CALR, MPL*) at day + 30 and + 180 posttransplant has been associated with an increased risk of relapse. In patients who lack molecular markers, incomplete or falling donor chimerism can be used to identify patients at risk for relapse. Use of preemptive donor-lymphocyte infusions (DLI) in these patients achieved complete molecular remission. Survival following relapse varies, with patients who relapse in the first 7 months having significantly poorer survival as compared to individuals who relapse later. DLI with or without chemotherapy, as well as a second HSCT, have been used with beneficial effects.

GF and PGF leading to increased risk of morbidity and mortality remain a challenge in patients with MF. GF occurs either due to primary failure to engraft or due to loss of donor cells following successful engraftment. Risk factors for GF include HLA mismatch, T-cell depletion, RIC, major ABO mismatch, and a low stem cell dose. Some of these patients experience autologous stem cell recovery with temporary improvement in disease control. Our group has demonstrated that a second HCT from the same or different donor can allow successful salvage in these patients. PGF, defined as cytopenias involving at least two cell lineages for at least 2 weeks in the setting of full donor chimerism and in the absence of relapse, GVHD, infection, or drug-related myelosuppression, affected 17% of patients in a retrospective study. Pretransplant splenomegaly and persistent splenomegaly after transplantation were identified as significant risk factors. Sequestration of stem cells in the spleen as well as alteration in homing proteins (such as VCAM-1 and CXCL12) are thought to contribute to delayed engraftment and PGF. In a retrospective study, CD34+ selected stem cell boost without prior conditioning resulted in hematological improvement in 81% of patients with hematological malignancies.

The feasibility of utilizing HSCT as the front-line therapy for all intermediate- and high-risk PMF patients is limited by the presence of competing comorbidities or a poor performance status due to the systemic effects of the underlying PMF. Although the JAK2 inhibitors are mostly palliative, they do reduce the degree of splenomegaly and often improve the performance status of such patients, frequently resulting in weight gain and improvement of their candidacy for HSCT. The reported outcomes with JAK2 inhibitor therapy as a component of the conditioning regimen for HSCT have resulted in conflicting results, with some studies showing improved posttransplant outcomes in patients with clinical response to ruxolitinib and others showing increased risk of GVHD, GF, and NRM.

The MPD-RC 114 two-stage, Simon, phase II trial of HSCT with preconditioning with intensive ruxolitinib therapy prior to a RIC regimen in patients with higher risk of MF with a primary endpoint of alive and engrafted was terminated prematurely because of poor accrual and significant GF (16%) and NRM (28%), as well as high rates of acute and chronic GVHD (64% and 76%). Since then, two small prospective studies have shown safety of ruxolitinib administration throughout conditioning and stable engraftment with low levels of aGVHD without increase in GFs. Further rigorous testing is required to determine the effects of JAK2 inhibition on immediate and long-term survival and transplant-related complications.

The fact that allogeneic RIC transplant is curative in appropriate patients is undeniable, and the improvements in the design of conditioning regimens, expansion of the donor pool, and supportive therapy makes this a viable first-line approach for individuals with advanced disease. Whether such an approach should also be implemented in patients with earlier phases of the disease, especially those with adverse cytogenetics or myeloid gene mutations, is a point of contention that requires further careful investigation since some of the adverse mutations have also been shown to have a negative impact on posttransplant outcomes.

Many unresolved issues remain to be clarified concerning the optimal strategy for HSCT in PMF. Understanding of peritransplant role of JAK2 inhibitors requires carefully designed prospective clinical trials. Outcomes of haploidentical donor transplants in management of PMF need to be compared to matched, unrelated donors in randomized prospective trial to determine the optimal donor in cases when both are available. Impact of molecular mutations on transplant outcomes require additional studies.

The need for splenectomy before HCT remains a major issue. Splenectomy before HSCT in PMF results in faster hematopoietic recovery but at the cost of potentially prolonged and complicated postoperative recovery. Although some analyses suggest improved survival with pretransplant splenectomy, it has also been associated with a potential increased risk of relapse. Moreover, even extensive splenomegaly (>30-cm longitudinal size by computed tomography scan) does not appear to prolong hematologic reconstitution after transplant.

The establishment of valid, complete remission criteria for PMF after HSCT remains a significant issue because the conventional criteria for response after HSCT are often influenced by GVHD, infections, or PGF and cannot be used. Conversely, normal blood counts and disappearance of disease-related symptoms do not exclude residual disease. In *JAK2* V617F-positive patients, the mutational allele burden following transplantation may serve as a surrogate marker for complete remission assessment and as a guide for instituting adoptive immunotherapy.

INVESTIGATIONAL THERAPEUTIC OPTIONS

Several targeted therapeutic agents aimed at modifying epigenetics, immunity, cellular survival, metabolic and apoptotic pathways, cell cycle, DNA repair, protein folding, and degradation are in various stages of clinical investigation. Aberrant methylation is commonly encountered in MPNs, which logically led to the evaluation of the DNA methyltransferase inhibitors in PMF. A phase II trial evaluated 5-azacitidine in 34 MF patients and showed an overall response rate of 24% after a median of 5 months of treatment. Grade 3/4 myelosuppression was seen in 29% of patients, requiring dose reduction in 47% of treated patients. Interestingly, there was no difference in global hypomethylation between responders and nonresponders, suggesting an alternative mechanism of action other than induction of DNA promoter site demethylation was responsible for the beneficial effects. Studies designed to evaluate the methylation status of specific genes thought to be silenced by this epigenetic modification (e.g., $p15^{INK4b}$ and $p16^{INK4a}$) need to be done in the future. Ruxolitinib with sequential addition of azacytidine from cycle 4 onwards and a gradual dose titration from 25 to 75 mg/m^2 daily for 5 days of each 28-day cycle showed preliminary activity in a phase II trial enrolling chronic phase MF. Seventy-four percent of treated patients achieved objective responses (OR) by IWG-MRT 2013 criteria, and 60% had greater than 1 grade reduction in BMF. Cytopenias were transient and only four patients discontinued treatment because of cytopenias (NCT01787487).

Histone deacetylase inhibitors (HDACi) downregulate JAK2 signaling by interfering with the chaperone function of heat shock protein 90 (HSP90) through modulation of acetylation. LBH589 (panobinostat) is a potent pan-deacetylase inhibitor that alleviated constitutional symptoms, reduced splenomegaly with improvement in hemoglobin, reduced BM reticulin and collagen fibrosis, and restored normal BM morphology in a small number of patients with PMF. However, a phase II study of panobinostat monotherapy at a dose of 25 mg BID was poorly tolerated and failed to show measurable clinical benefit. A phase I trial (PRIME) reported the safety and efficacy of the combination of ruxolitinib and panobinostat in 15 patients with MF. Forty percent of the treated patients experienced clinical improvement (spleen $n = 5$, anemia $n = 1$), and this combination was found to be safe and tolerable without dose-limiting thrombocytopenia. The MTD of both agents, in combination, was not determined. Further development of this combination has been hampered by modest activity and the need to determine the optimal dosing schedule of panobinostat to avoid myelosuppression and maximize on-target activity.

Modifying the dysregulated transcriptome (e.g., c-Myc, NF-kB overexpression) in MF through inhibition of bromodomain extra terminal (BET) proteins appears to be an exciting therapeutic strategy. Preclinical studies in MF demonstrated synergistic activity between ruxolitinib and the small-molecule BET protein inhibitor JQ1 with a reduction of inflammatory cytokine production, disease burden, and reversal of BMF in an MPL-driven murine model of MF. CPI-0610 is an oral pan-BET protein inhibitor that is being evaluated as monotherapy and in combination with ruxolitinib in patients who have failed and discontinued ruxolitinib, with a suboptimal response, or are naïve to JAK inhibition (NCT02158858). As the preclinical models would predict, activity in terms of SVR35% (29%) and TSS50% (77%) was most notable in the combination arm and particularly impressive in those that were RBC transfusion-dependent at baseline, with 42% of treated patients achieving transfusion independence.

HOW SHOULD PRIMARY MYELOFIBROSIS PATIENTS WITH THROMBOCYTOPENIA BE TREATED?

Platelet Count 50–100 × 10⁹/L

It is important to be certain that vitamin B_{12} or folate deficiencies and/or sustained suppression from prior chemotherapeutic agents are not contributing to the development of a low platelet count. Chemotherapeutic agents such as hydroxyurea can be used in patients with marked splenomegaly, which can result in an improvement in the platelet count as the spleen volume is reduced. Patients can also be treated with thalidomide or lenalidomide in combination with prednisone. These first-generation IMiDs can sometimes improve cytopenias and reduce splenomegaly in PMF patients, and in some cases, this response can persist even after drug discontinuation. Lenalidomide can induce cytopenias to a greater extent than thalidomide, which needs to be taken into consideration before its use in a thrombocytopenic patient. In a randomized phase III trial, pomalidomide failed to meet the primary endpoint of anemia response (transfusion independence: ≥84 days), but the platelet response rate was 22% in the treatment arm. This finding supported the previous phase II findings of a response rate of 58% in increasing the baseline platelet count by greater than 50% in patients with baseline platelets above 50 × 10^9/L. This second-generation IMiD has not been evaluated in patients with platelet counts below 50 × 10^9/L. A course of prednisone therapy should also be considered, since 30% to 40% of patients have been reported to respond to this agent alone.

Ruxolitinib has more recently been shown to be safe and effective in patients with baseline platelet counts as low as 50 × 10^9/L, and the FDA label has been expanded to include such MF patients. Sustained thrombocytopenia with ruxolitinib therapy is an indication for a dose reduction or discontinuation of the drug. Patients can also be enrolled in other JAK2 inhibitor clinical trials in which reduced platelet counts are acceptable (such as the PACIFICA phase III pacritinib trial) or other agents in clinical development. If thrombocytopenia worsens with the current treatment plan, then proceed with the strategy outlined below.

Platelet Count 20–50 × 10⁹/L

Thalidomide or lenalidomide, in combination with prednisone, can be used to correct anemia in these PMF patients but rarely improves the platelet counts in a clinically meaningful way. Most clinical trials involving a variety of therapeutic agents, including JAK2 inhibitors, will require baseline platelets above 50 × 10^9/L. In patients who are experiencing life-threatening bleeding, in addition to aggressive, immediate platelet transfusions, splenectomy is a reasonable therapeutic option. Pacritinib, as first-line JAK inhibitor therapy in JAK inhibitor-naïve MF patients with baseline platelet counts <50 × 10^9/L or AVID200 in those previously treated with a JAK inhibitor, would be a clinical trial consideration.

Platelet Count <20 × 10⁹/L

Treatment choices are truly limited for these patients. Intervention is also dependent on the clinical picture, with emphasis on addressing bleeding. Supportive therapy with frequent platelet transfusions is a possibility, but it is likely not sustainable in the long term. It is our practice to transfuse if the platelet count is below 10 × 10^9/L unless there is no evidence of mucosal bleeding or life-threatening hemorrhage. Occasionally, patients may have an improvement in the degree of thrombocytopenia with steroids. About 20%–30% of patients with severe thrombocytopenia will have significant improvement in platelet counts after a splenectomy. Aggressive platelet transfusional support is necessary before, during, and after splenectomy in many cases. However, splenectomy in patients with PMF is associated with a postoperative morbidity rate of 15%–30% and a mortality rate close to 10%. These numbers, however, are highly dependent on the institutional experience and the operating surgeon. Splenectomy can also result in EMH in the liver, causing hepatomegaly, which may require the administration of a judicious amount of chemotherapeutic agents (hydroxyurea, busulfan, and cladribine) or a JAK2 inhibitor. Severe thrombocytopenia is an adverse prognostic feature. Such patients who are eligible for HSCT and have available donors should be considered for immediate transplantation. Thrombopoietin mimetics have been associated with increased bone marrow fibrosis when used for the treatment of immune thrombocytopenic purpura and have not been formally evaluated in the setting of PMF-associated thrombocytopenia. Additionally, patients with extreme thrombocytopenia and signs of leukemic transformation can be considered for therapy with decitabine or azacitidine with aggressive platelet transfusional support. They then, ideally, should proceed to allogeneic HCT if a donor is available and the patient's performance status is appropriate.

WHICH PATIENTS SHOULD BE CONSIDERED FOR ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION?

Allogeneic hematopoietic stem cell transplantation (HSCT) is the only potential curative treatment option for primary myelofibrosis (PMF). Patients with poor-risk features and decreased probability of survival should be considered for HSCT because the risk of transplant-related morbidity and mortality is not insignificant. All patients younger than 70 years of age and their siblings should be typed for human leukocyte antigens at the time of diagnosis to determine if there is a potential match. Patients between the ages of 65 and 70 years old with available related donors should be evaluated based on their performance status and the presence of comorbid conditions. Patients younger than 70 years of age with good performance status and available donors (either related or fully matched unrelated) should be encouraged to undergo evaluation for HSCT soon after the diagnosis and preferably within a clinical trial. Patients with a high- or intermediate-risk disease with available donors should consider transplantation before developing debilitating symptoms or significant worsening in their performance status. Patients with low-risk disease can be closely monitored without intervention but should proceed to transplantation with evidence of disease progression. For patients with available donors but poor performance status because of the symptoms of myelofibrosis, a course of ruxolitinib can be considered with the goal of improvement in performance status associated with the reduction of splenomegaly and constitutional symptoms. These patients may become more viable transplant candidates with this pretransplant treatment approach. Splenectomy before transplant is not essential to ensure adequate engraftment. Currently, HSCT using reduced-intensity conditioning regimens, haploidentical donors, and cord blood grafts is being actively evaluated.

WHICH PRIMARY MYELOFIBROSIS PATIENTS ARE APPROPRIATE FOR JAK2 INHIBITOR THERAPY?

Not all PMF patients require treatment with JAK2 inhibitor therapy. Patients with symptomatic splenomegaly or debilitating MF-related symptoms are potential candidates for treatment with ruxolitinib or fedratinib. The inhibition of JAK1/2 is associated with myelosuppression and could further compromise existing cytopenias. In patients with isolated splenomegaly and adequate blood counts, a course of hydroxyurea could be considered. If the patient fails hydroxyurea or has debilitating symptoms, then ruxolitinib/fedratinib would be the appropriate agent. Both ruxolitinib and fedratinib are currently approved for patients with intermediate- and high-risk MF and have yet to be formally explored in cases of symptomatic patients with low-risk disease. Additionally, the use of these drugs are not advised in MF patients with platelet counts below 50 × 10^9/L. Ruxolitinib/fedratinib should be used in patients with a poor performance status before HSCT as a means to improve their performance status and promote weight gain in an attempt to optimize them for SCT. Although the COMFORT 1 trial reported a modest improvement in survival at a median of 51 weeks of treatment with ruxolitinib, the exact mechanism that underlies this survival benefit remains unknown, and this agent should not be given with the primary goal of disease process modification and promoting increased survival. Patients started on ruxolitinib need to have frequent monitoring of blood counts. If discontinued, the dose should be either tapered or accompanied by a pulse of concurrent steroid therapy to avoid the life-threatening rebound of systemic symptoms and splenomegaly, which can occur at times.

Fedratinib is approved in the United States as a front-line JAK2 inhibitor option as well as the second line in the treatment of MF. A patient can be safely switched from ruxolitinib to fedratinib, without tapering, to address suboptimal spleen/symptom response or loss of initial response. As with ruxolitinib, blood counts have to be monitored frequently. Gastrointestinal side effects are common but mitigated by antiemetics, and these adverse effects decrease over continued fedratinib administration.

HOW DOES CHARACTERIZING THE MUTATIONAL PROFILE OF A PRIMARY MYELOFIBROSIS PATIENT INFLUENCE CARE?

Assessing the status of the driver mutations *JAK2*, *MPL*, and *CALR* in PMF can help refine prognostication and influence therapeutic decision making. Retrospective studies suggest that molecular risk stratification can further refine the individual risk for leukemic transformation and overall survival. Patients with triple negative status (lacking mutations of *JAK2*, *MPL*, and *CALR*) or with an *ASXL1* mutation are at the highest risk for a poor outcome. They should be evaluated for early HSCT or experimental therapy even if they are assessed to have a low-risk disease by conventional risk-stratification tools. Such patients should be sent for transplant at the earliest time of evidence of disease evolution. It is also important to remember that *JAK2* wild-type status, and *MPL*- and *CALR*-mutated patients respond equally well to ruxolitinib therapy. The characterization of nearly 20 recurrent gene mutations in PMF patients implicates a complex and heterogeneous molecular pathophysiology that will likely not allow for a single therapeutic target drug approach. Whether the presence of certain specific gene mutations will ultimately predict a therapeutic response with different agents has yet to be shown. The presence of these mutations can also be used to detect minimal residual disease after HCT. The combination and number of mutations adversely affect the outcomes in a patient with PMF. *TP53* mutations are rare in chronic phase MF (~5%), but more frequent at the time of transformation to AML. Additionally, those with *ASXL1* and non-*CALR/MPL* mutations also suffer from poor outcomes. PMF patients who harbor *TP53, ASXL1*, or non-*CALR/MPL* mutations should undergo HCT evaluation early in their disease course.

Approximately one-third of treated patients also attained at least one grade reduction in bone marrow fibrosis. A cohort of ruxolitnib-naïve patients was treated with combination therapy and initial results are very encouraging with a SVR35% of 70%. Myelosuppression was minimal and Grade 3/4 anemia and thrombocytopenia occurred in 7% and 10% of treated patients, respectively.

Another epigenetic target of interest in MF is lysine-specific demethylase 1 (LSD1). In preclinical studies, bomedemstat (IMG-7289), an irreversible LSD1 inhibitor, selectively abrogated proliferation and induced apoptosis of *JAK2*^{V617F} cells, normalized blood counts, and reduced bone marrow fibrosis. Bomedemstat is currently under clinical investigation in patients with MF who are resistant or intolerant to ruxolitinib. Fifty percent (7/14) of treated patients achieved a modest SVR, and 79% (11/14) had TSS improvement. Bomedemstat was reasonably well tolerated and is undergoing further clinical evaluation (NCT03136185).

JAKs regulate the antiapoptotic protein BCL-XL; the subsequent demonstration of synergism with JAK2 and BCL-2/-XL inhibition in preclinical *JAK2*^{V617F} MPN models has prompted the investigation of antiapoptotic agents in MF. A phase II clinical trial of navitoclax and ruxolitinib in patients with MF showed preliminary efficacy (30% [9/30] achieved SVR35%, 65% [11/17] experienced reduction in TSS, and 25% had >1 grade reduction in BMF), and the evaluation is ongoing (NCT03222609). On target, thrombocytopenia was observed and was manageable. Another agent of clinical interest targeting the apoptotic pathway is the second mitochondrial activator of caspases (SMAC)-mimetic. The SMAC mimetic LCL-161 antagonizes the inhibitor of apoptosis (IAP) proteins, thereby targeting a different arm of the antiapoptotic machinery. LCL-161 is being evaluated in ruxolitinib-pretreated or ruxolitinib-ineligible patients with MF. Thirty percent (9/30) had OR by IWG-MRT 2013 criteria, with 20% attaining improvement in TSS. Weekly dosing schedule was well tolerated. Further evaluation is ongoing (NCT02098161).

A novel and exciting therapeutic approach to the treatment of MF is an infusional telomerase inhibitor, imetelstat, which is a 13-mer lipid-conjugated oligonucleotide competitive inhibitor of telomerase RNA (hTR), resulting in telomere shortening and cell cycle arrest and apoptosis. A pilot study of imetelstat in 33 patients with MF reported complete morphologic and molecular remissions even in those harboring HMR mutations. The occurrence of elevated liver function tests led to an initial study hold, whose release was followed by the large, multicenter randomized phase II IMbark trial (NCT02426086) that evaluated two dose levels (9.4 and 4.7 mg/kg) of imetelstat in patients with MF who were refractory to or had relapsed after treatment with a JAK inhibitor. The low-dose arm was closed due to a lack of clinical efficacy. Imetelstat 9.4 mg/kg administered intravenously every 3 weeks was well tolerated and demonstrated clinical activity (10% SVR35%, 30% TSS50%), but most importantly, it was associated with a median OS that approached 30 months, which is double the reported median OS in patients who are resistant to JAK2 inhibitors (12 to 14 months). This survival advantage was seen across all molecular risk categories, including triple negative patients. Baseline short telomeres increased telomerase activity and increased hTERT RNA expression level predicted response and pharmacodynamic biomarkers of response, such as reduction in telomerase activity, were enriched in clinical responders, which also included reductions in BMF grade. Given the encouraging results, a global phase III clinical trial of imetelstat in MF patients refractory to JAK2 inhibitor therapy will be initiated with an OS primary endpoint. Of note, the imetelstat phase III trial will be the first study in the clinical investigation of MF to have OS as the primary endpoint.

FUTURE DIRECTIONS

More rational therapies for PMF are evolving from an increased understanding of the cellular and molecular biologic abnormalities underlying PMF. Studies defining the relative contributions of acquired genetic mutations, epigenetic events, as well as the influence of the BM and splenic microenvironment on the origins of PMF, disease progression, and events leading to leukemic transformation are ongoing. Because PMF originates at the level of the HSC, the identification of novel drugs that eliminate such malignant stem cells is likely the most direct route to potentially curative pharmacologic strategies. The evaluation of the use of a combination of active agents, including the JAK2 inhibitors, TGF-β inhibitors, IMiDS, HDACi, BETi, antiapoptotic agents, and telomerase inhibitors, is anticipated to lead to significant clinical improvements in the outcomes of PMF patients. The evaluation of these combination therapies will undoubtedly require the use of novel strategies for the design of clinical trials that will evaluate the effects of several active agents administered either simultaneously or sequentially, and meaningful endpoints such as survival and progression-free-survival will need to be considered. Overall, the implementation of any therapeutic approach by the practicing community of hematologists should only occur after evidence is provided by the completion of well-planned and adequately powered phase III trials comparing the experimental approach to the standard of care.

HSCT remains the only potentially curative therapy available for patients under 70 years of age with acceptable performance status and a suitable available donor. Although there is a reluctance to expose PMF patients to the risks of HSCT if their underlying disorder is associated with a sufficiently poor prognosis, this risk appears to be warranted. Because early forms of PMF are associated with survival of well over a decade, many hematologists have been even more reluctant to expose such patients to experimental therapeutic agents or HSCT. Unfortunately, progression to more advanced forms of MF is anticipated in younger patients. Exploration of therapeutic agents that can delay or even prevent disease progression or identification of the appropriate role of HSCT in this low-risk group will require additional study. Such trials will be time-consuming due to the prolonged survival of such patients with low-risk disease. The decision to proceed to transplant requires a detailed discussion of the risks and benefits of such a high-risk but potentially curative procedure.

The recent establishment of multiinstitutional cooperative groups to evaluate such novel therapies and treatment strategies for PMF patients has met the need of ensuring rapid evaluation of candidate therapeutic agents. No single institution has sufficient numbers of patients to perform this ever-growing number of required investigative efforts. Only with the completion of such rigorous evaluations of individual therapeutic strategies will one be able to determine the value of a continuously growing number of potentially active agents used alone or in combination. Each new therapy will likely be evaluated using not only a number of clinical endpoints but also surrogate biomarkers and consideration of the immediate and long-term toxicities associated with their documented use. Independently developed objective criteria by which responses to experimental therapeutic agents can be judged must be implemented for the evaluation of promising agents. Furthermore, incorporation of validated QoL tools into the clinical trials provides patient-reported outcome data, which is invaluable in assessing the efficacy of novel therapeutic agents. Efforts must be made to evaluate these new classes of agents in the preconditioning regimens for HSCT as this approach may contribute to significant improvements in outcomes in PMF patients undergoing HCT.

CHRONIC NEUTROPHILIC LEUKEMIA

Chronic neutrophilic leukemia (CNL) is a rare Philadelphia chromosome-negative MPN characterized by sustained, mature neutrophilic leukocytosis and bone marrow granulocytic hyperplasia, often accompanied by hepatosplenomegaly. The true incidence of CNL remains unknown, with less than 300 reported cases in the literature, thus attesting to its rarity. CNL is predominantly a disease of older age, with a median age of diagnosis at 66.5 years and a slight predilection for males. CNL was first described by Tuohy in 1920 in a female with symptomatic splenomegaly and mature neutrophilic leukocytosis noted on the peripheral smear. Tanzer et al. in 1964 put forth the terminology “Chronic neutrophilic leukemia of mature cell type” when they described a patient with mature neutrophilia and massive splenomegaly in the absence of t (9;22). Although the WHO recognized CNL as a distinct MPN in 2001, it was only after the discovery of mutations involving the colony-stimulating factor 3 receptor (CSF3R) oncogene in 2013, that the diagnostic criteria for CNL were formalized and the disease was seen as distinct diagnosis with a defined biomarker.[16]

MOLECULAR PATHOGENESIS OF CHRONIC NEUTROPHILIC LEUKEMIA

The growth factor, granulocyte colony-stimulating factor (G-CSF), now referred to as CSF3, principally regulates neutrophil production in basal and emergency conditions (in response to infection, and stress). CSF3R belongs to the cytokine receptor type I superfamily and exploits the canonical Janus kinase (JAK)-STAT signaling pathway, among others. Direct evidence for a possible role of CSF3 in propagating leukemic evolution materialized from patients with severe congenital neutropenia (SCN) (see Chapter 31). Approximately 80% of SCN patients were known to harbor frameshift or nonsense mutations of *CSF3R* that truncate the cytoplasmic tail of CSF3R at the time of leukemic transformation. These truncation mutations were thought to hamper normal neutrophil differentiation and instead allow for unchecked neutrophilic proliferation. Occasionally, these truncation mutations are accompanied by an activating point mutation in the proximal membrane domain of *CSF3R* in addition to the truncation mutation. It is postulated that *CSF3R* mutations in SCN provide a clonal advantage to the hematopoietic stem cell through oncogene cooperativity.

Maxson et al. hypothesized that patients with CNL or atypical CML may harbor oncogenes sensitive to small-molecule kinase inhibitors. They used an elegant, integrated approach of deep sequencing coupled with the screening of primary leukemia cells obtained from patients with CNL or atypical CML against panels of tyrosine kinase-specific, small interfering RNAs or small-molecule kinase inhibitors. The deep sequencing screen identified *CSF3R* mutations in 16 of 27 patients with CNL (89%) and atypical CML (40%). Two mutational variants were reported: the more common membrane proximal, point mutations consisting primarily of *CSF3R* T618I and T615A variants, and frameshift or nonsense mutations leading to premature truncation of the cytoplasmic tail of CSF3R (D771fs, S783 fs, Y752X, and W791Z). The truncation mutations, which also occur in SCN, largely coexisted with membrane proximal or transmembrane *CSF3R* mutations as compound mutations.

Next, they sought to determine if *CSF3R* mutations showed in vitro sensitivity to small molecule tyrosine kinase inhibitors or small interfering RNA directed against kinases known to be activated by normal CSF3R. While frameshift or nonsense mutations result in dysregulation of SRC and TNK2 kinases (and thus were sensitive to the multikinase inhibitor dasatinib), membrane-proximal mutations appeared to cause ligand-independent hyperactive JAK-STAT signaling and were susceptible to the JAK inhibitor ruxolitinib.

Mechanistically, truncation mutations lead to loss of negative regulatory motifs, namely the di-leucine internalization motif in the cytoplasmic domain of the CSF3R and the binding site for suppressor of cytokine signaling 3 (SOCS3), resulting in decreased lysosomal trafficking of the receptor. This, in turn, increases the cell-surface expression of CSF3R, thus conferring ligand hypersensitivity and sustained neutrophil proliferation. In contrast, the membrane-proximal mutations prevent *O*-glycosylation of CSF3R, resulting in ligand-independent homodimerization, constitutive activation of JAK-STAT signaling pathway and resultant autonomous cell proliferation. Fleishman et al., through a murine transplant model, established the role of *CSF3R* T618I as an oncogenic driver in CNL. The *CSF3R* T618I murine transplant model developed a myeloproliferative disorder akin to CNL that was uniformly fatal.[17] Treatment with the JAK1/2 inhibitor ruxolitinib decreased the white blood count and reduced spleen weight, suggesting that activating mutations in *CSF3R* are sensitive to pharmacologic JAK inhibition. Taken together, these studies indicate that the type of *CSF3R* mutation influences sensitivity to different mechanism-based therapeutic agents, thus providing a rationale for molecularly directed therapeutic targeting in CNL.

Approximately 33% of patients harbor dual truncation and membrane-proximal mutations on the same allele (compound mutation). They rely on the mitogen-activated protein kinase (MAPK) pathway for oncogenic signaling and leukemogenesis. These compound mutants are characteristically impervious to ruxolitinib or dasatinib, given their reliance on MAPK signaling, and are predictably sensitive to MEK1/2 inhibitor trametinib. These results demonstrate the oncogenic role of MAPK signaling in patients with *CSF3R* compound mutations.[18]

Additional mutations involving the spliceosome complex and epigenetic modification, genes that govern cell proliferation, growth factors, and kinase signaling are also known to occur in CNL. The cooperative role of these mutations in the pathogenesis of CNL and their prognostic significance are yet to be determined (Table 72.8).

CLONAL EVOLUTION

Zhang and colleagues, using WES and RNA sequencing (RNA-seq), characterized the genomic profile, including co-occurrence and the order of mutational acquisition in CNL, atypical CML, and other MPN/MDS overlap syndromes.[19] The median number of mutations observed per patient was 3.6, suggestive of a byzantine genomic landscape in these related disorders. *CSF3R* mutations frequently tend to co-occur with *SETBP1* and ASXL1 in CNL. Upon analysis of the clonal architecture of patients harboring *SRSF2*, *ASXL1*, and signaling gene mutations, they observed that *SRSF2* mutations were present in the dominant clone, whereas signaling genes and *ASXL1* mutations were observed variably in the dominant clone and subclones in some cases. A similar pattern was also observed in patients with *EZH2*, *TET2*, and signaling gene mutations.

TABLE 72.8 **Frequency of Concurrent Mutations Reported in CSF3R-Mutated Chronic Neutrophilic Leukemia**

Mutation	Frequency (%)
SETBP1	41
JAK2/CBL/SH2B3	7.7/5.1/0.0
NRAS/KRAS	10.3/0.0
DNMT3A/TET2/ASXL1	5.1/20.5/76.9
SRSF2/U2AF1	43.6/15.4
EZH2	20.5
TP53/PTPN11	2.6/10.3

Adapted from Zhang H, Wilmot B, Bottomly D, et al. Genomic landscape of neutrophilic leukemias of ambiguous diagnosis. *Blood*. 2019;134(11): 867–879.

In most cases, variant allele frequencies (VAF) of two of the three pathway mutations were greater than 50%, suggesting the co-occurrence of these mutations in the dominant clone. The third mutation, present at a lower VAF, suggests latter acquisition in a subclone harboring both original mutations. This finding supports a linear evolution of a single, dominant clone, unlike AML, where multiple independent subclones are observed with a branching pattern of mutational acquisition. Moreover, 19% of patients harbored ≥2 different signaling pathway mutations: one where *CSF3R* was shown to cooccur with *NRAS*, *CBL*, *PTPN11*, *SH2B3*, *NTRK2*, and *ABL1* mutations; and the second where *NRAS* mutations co-occurred with *CSF3R*, *KRAS*, *JAK2*, *CBL*, *STAT3*, *NTRK2*, *FLT3*, and *GNB1* mutations. VAF analysis demonstrated that the majority of signaling pathway mutations were present in the same clone. Drug sensitivity assays of cells transformed by coexisting *CSF3R* and *NRAS* mutations demonstrated reduced drug sensitivity to either ruxolitinib (*CSF3R*) or a MEK inhibitor, trametinib (*NRAS*), which was salvaged by combination ruxolitinib and trametinib treatment targeting both pathways, suggesting that these signaling mutations represent important therapeutic targets in CNL.

Furthermore, Stoner et al. analyzed the mutational patterns of seven CNL patients with disease progression on ruxolitinib therapy to understand the changes in the clonal architecture of CNL. In three patients, *RUNX1* mutations were detected at the time of AML transformation but not at baseline. Additionally, an earlier anecdotal report mentions *RUNX1* clonal expansion at the time of disease progression (WBC, splenomegaly) without AML transformation in a CNL patient receiving ruxolitinib therapy. Collectively, this data suggests that *RUNX1* may cooperate with *CSF3R* mutation to drive disease progression and may even be an early marker of AML transformation. Moreover, *STAT3* and *CBL* subclonal expansion have been detected in patients who lost their initial response to ruxolitinib. Further research is needed to clarify the disease-causing properties of these subclones and their contribution to ruxolitinib resistance in CNL.

CLINICAL AND LABORATORY FEATURES OF CHRONIC NEUTROPHILIC LEUKEMIA

The clinical features of CNL resemble any other MPN with a constellation of constitutional symptoms: fatigue, bone pain, pruritus, gout, and symptomatic splenomegaly. Patients with CNL are prone to bleeding diathesis due to quantitative or qualitative (acquired von Willebrand disease) dysfunction.

Laboratory findings of CNL are characterized by sustained, chronic, mature neutrophilic leukocytosis in the absence of monocytosis, basophilia, or eosinophilia. In contrast to CML, leukocytosis in CNL consists of mainly mature neutrophils without a left shift. Circulating blasts are not seen in CNL. Mild anemia may be seen. Mild thrombocytopenia may be seen with disease progression and development of splenomegaly. Uric acid, lactate dehydrogenase (LDH) levels, as well as the LAP score are typically elevated. Vitamin B12 levels are also often elevated due to transcobalamin release from granulocytes and their precursors.[20]

A bone marrow biopsy is essential to diagnose CNL (Fig. 72.13). The bone marrow is usually hypercellular for patients with absolute myeloid hyperplasia (myeloid-to-erythroid ratio often exceeding 20:1). There is abundant granulocytic proliferation with increased myelocytes, metamyelocytes, bands, and segmented neutrophils but without significant granulocytic or myeloid dysplasia. Blasts and promyelocytes are not increased. Normoblastic erythroid precursors are seen but reduced. Megakaryocytes are morphologically normal. Reticulin fibrosis is not typical. Association with other myeloid and lymphoid disorders is suggested, most commonly polycythemia vera and plasma cell disorders, where either entity may be present concurrently with CNL. Therefore it is suggested to examine CNL bone marrow carefully for nonclonal plasma cell populations.

Hepatosplenomegaly is caused by neutrophilic infiltration in the tissues. In the spleen, the infiltration is limited to red pulp cords and sinuses, resembling a leukemic pattern, whereas in the liver, the sinuses, or portal areas, or both, may be infiltrated.

Most patients with CNL exhibit a normal karyotype at diagnosis, and CGAs are usually observed during clonal evolution. Most common CGAs include trisomy 8, trisomy 21, deletion 11q, and deletion 20q, which are not specific to CNL but observed in myeloid malignancies. Identification of *CSF3R*-activating mutations through NGS clinches the diagnosis of CNL.

DIAGNOSIS

According to the most recent WHO criteria, CNL is defined by mature neutrophilic leukocytosis (≥25 × 10^9/L) and neutrophil precursors comprising less than 10% of white blood cell count; absent to minimal monocytosis and dysgranulopoiesis; hypercellular bone marrow with less than 5% myeloblasts; presence of CSF3R T618I or other activating CSF3R mutation; and absence of BCR-ABL1, PDGFRA, PDGFRB, or FGFR1 rearrangement or PCM1-JAK2 and classic MPNs (i.e., PV, ET, PMF) (Table 72.9).[21] In patients lacking a CSF3R mutation, CNL is established by sustained neutrophilia (at least 3 months) or by splenomegaly with no appreciable cause of reactive neutrophilia without plasma-cell neoplasm. If neutrophilia occurs in the setting of a plasma-cell dyscrasia, clonality of myeloid cells must be documented. The absence of monocytosis, lack of marrow dysplasia and less than 10% circulating myeloid precursor cells, and presence of a CSF3R-activating mutation differentiate CNL from a CML or CMML.

DIFFERENTIAL DIAGNOSIS

Neutrophilic leukocytosis may either be benign or malignant (Fig. 72.14). CNL diagnosis must be carefully distinguished from reactive neutrophilia/leukemoid reaction, CML, neutrophilic-CML (CML-N), and MPN/myelodysplastic (MDS) overlap disorders such as atypical chronic myeloid leukemia (aCML) and CMML (Table 72.10).

PROGNOSIS

Overall prognosis of CNL is poor, with a median OS of 24 months in untreated patients. Life-threatening complications include intracranial hemorrhage, progressive disease, leukemic transformation,

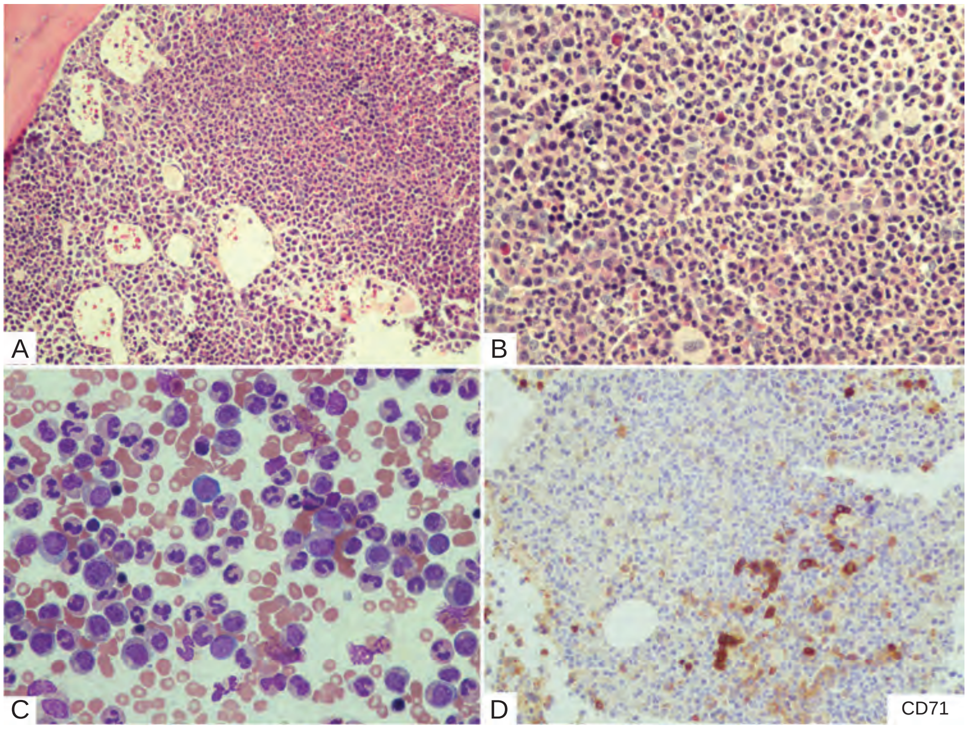

Figure 72.13 BONE MARROW BIOPSY IN CHRONIC NEUTROPHILIC LEUKEMIA. (A and B) Low- and high-power images showing the hypercellular marrow and the myeloid hyperplasia with high numbers of mature neutrophils. (C) Bone marrow smear showing the myeloid hyperplasia with mostly mature forms and no increase in the immature forms. (D) CD71, an erythroid precursors marker, showing decreased and sparse erythroid colonies, indicative of the high myeloid to erythroid ratio.

and treatment-related toxicity following chemotherapy or HCT. Progressive disease is characterized by loss of therapeutic response, progressive refractory neutrophilia, increasing transfusion requirements, acquisition of additional molecular or CGA, and eventually AML. The median time to AML transformation is 21 months (3 to 94 months), and occasionally CNL may transform to PV or CMML.

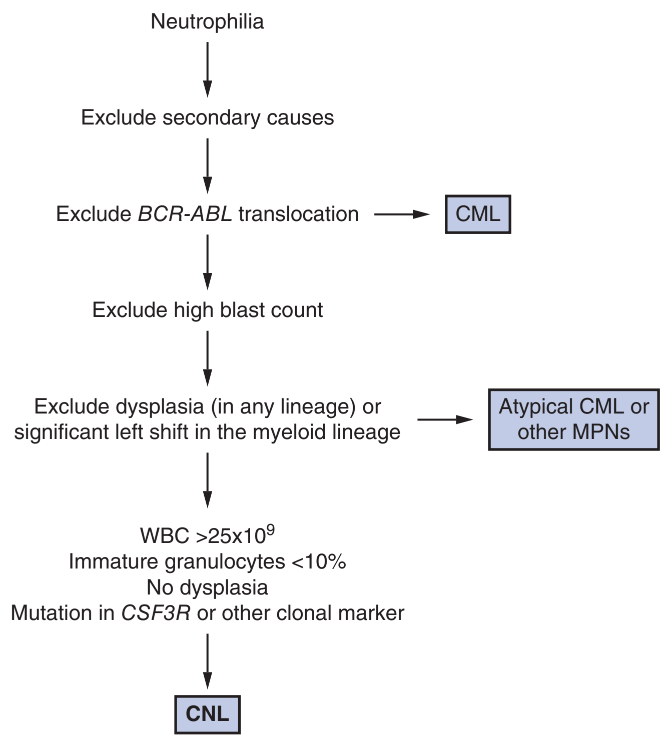
Thus far, a prognostic scoring system has not been validated for risk stratification in CNL. The Mayo Clinic group developed the first prognostic model predictive of long-term survival in CNL, capturing data from 19 *CSF3R*-mutated, molecularly annotated patients.[22] In this model, platelets less than 160 × 10^9/L (2 adverse points), leukocytes greater than 60 × 10^9/L (1), and presence of an ASXL1 mutation (1) maintained their statistical significance as negative prognostic factors in both univariate and multivariate analyses. When patients were allocated to low-risk (0 to 1 points; $n = 9$) or high-risk (2 to 4 points; $n = 10$) categories, OS times were "not yet reached" and 22.4 months ($P = .0016$), respectively. Zhang et al. further elucidated that *NRAS, ASXL1, GATA2*, and *DNMT3A* mutations were associated with a trend towards shorter OS, while *CBL* mutations predicted favorable survival in CNL.

TABLE 72.9 **WHO Diagnostic Criteria for Chronic Neutrophilic Leukemia**[6]

1. Peripheral blood leukocytosis, ≥25 × 10^9/L
    - Segmented neutrophils plus band forms ≥80% of WBCs
    - Neutrophil precursors (promyelocytes, myelocytes, and metamyelocytes) <10% of WBC
    - Myeloblasts rarely observed
    - Monocyte count <1 × 10^9/L
    - No dysgranulopoiesis
2. Bone marrow biopsy that shows a greater than normal percentage of bone marrow cells
    - Neutrophils increased in percentage and number
    - Neutrophil maturation appears normal
    - Myeloblasts (immature cells) <5%
3. Not meeting WHO criteria for CML *BCR-ABL1*-positive CML, PV, ET or PMF
4. No genetic rearrangement (mutation) of *PDGFRA, PDGFRB*, or *FGRF1*, or *PCM1-JAK2*
5. Presence of CSF3R T618I or other activating CSF3R mutation, or in the absence of a CSF3R mutation:
    - Persistent neutrophilia (at least 3 months)
    - Enlarged spleen (splenomegaly)
    - No identifiable cause of reactive neutrophilia including absence of a plasma cell neoplasm
    - If reactive neutrophilia is present, demonstration of malignant myeloid cells by cytogenetic or molecular studies

MANAGEMENT OF CHRONIC NEUTROPHILIC LEUKEMIA

There is no standard of care for the effective management of CNL. Given the noticeable lack of established treatment guidelines, clinical trial participation is suggested whenever feasible. HSCT remains the definitive curative therapeutic strategy in those patients who are eligible, and available chemotherapeutic agents do not improve OS.



Neutrophilia
Exclude secondary causes
Exclude BCR-ABL translocation
CML
Exclude high blast count
Exclude dysplasia (in any lineage) or significant left shift in the myeloid lineage
Atypical CML or other MPNs
WBC >25x10^9
Immature granulocytes <10%
No dysplasia
Mutation in CSF3R or other clonal marker
CNL

TABLE 72.10 **Differential Diagnosis of Chronic Neutrophilic Leukemia**

Characteristic	CNL	aCML	CMML	CML-N
Philadelphia chromosome	–	–	–	+
Proliferating cells	Mature neutrophils	Neutrophils	Monocytes and neutrophils	Granulocytes and megakaryocytes
Dysplasia	No	Trilineage dysplasia	More than one lineage	Minimal to absent
Blasts in peripheral blood or bone marrow	0%–5%	<20%	<20%	<10%
Genetic abnormality	*CSF3R* mutation	*SETBP1* and/or *ETNK1* in ~ 35% of patients and *CSF3R* in <10%	*SETBP1, TET2, ASXL1, SRSF2*	*BCR-ABL* rearrangement resulting in p230 transcript

CNL, Chronic neutrophilic leukemia; *aCML*, atypical chronic myeloid leukemia; *CMML*, chronic myelomonocytic leukemia; *CML-N*, chronic myelogeneous leukemia:neutrophilic variant

Cytoreductive therapy is recommended in patients deemed unfit for HSCT or clinical trials, or those with highly symptomatic CNL. Historically, splenic irradiation and splenectomy were used as therapeutic options in CNL patients with symptomatic splenomegaly. However, given the risk of postoperative neutrophilic leukocytosis, splenectomy as a therapeutic option is no longer recommended. In a retrospective case series of 40 patients, hydroxyurea was the most common first-line chemotherapeutic agent (80%), and approximately 75% of the patients treated experienced clinical improvement in terms of reduced leukocytosis and/or splenomegaly, with a median response of 12 months (range, 1 to 87 plus months). IFN-α has been shown to be tolerable and provide a durable response lasting 25 months (range, 16 to 41 months) even in the setting of hydroxyurea refractoriness.[23]

Ruxolitinib is currently approved for treatment of patients with intermediate- or high-risk MF, and for PV patients intolerant or refractory to hydroxyurea. Due to inhibition of the oncogenic JAK-STAT signaling pathway, ruxolitinib was hypothesized to provide clinical benefit in CNL patients. Dao et al. evaluated the safety and efficacy of ruxolitinib in patients with CNL and aCML, irrespective of *CSF3R* mutation status.[24] In this phase II study of 44 patients (21 CNL and 23 aCML) that utilized a Simon's two-stage minimax design, the primary endpoint was overall hematologic response rate (ORR includes complete response-CR and partial response-PR) by the end of six continuous 28-day cycles for the first 25 patients enrolled, and the secondary endpoints included grade ≥3 adverse events, spleen volume, symptom assessment, genetic correlates of response, and 2-year survival.

Ruxolitinib was well tolerated and demonstrated an estimated response rate of 32% for the first 25 enrolled patients (8 PR [7 CNL and 1 aCML]). In the larger cohort of 44 patients, 35% had a response (11 PR [9 CNL and 2 aCML] and 4 CR [CNL]). Compared to wild-type, *CSF3R*-mutated CNL patients achieved a greater reduction in white blood cell count and SVR35% with ruxolitinib treatment, suggesting that *CSF3R* mutations in CNL are sensitive to ruxolitinib therapy. Grade ≥3 anemia and thrombocytopenia were observed in 34% and 14% of patients, respectively. No serious adverse events attributed to ruxolitinib were observed. Median OS was 23.1 months vs. 15.6 months for responders and nonresponders, respectively. These results suggest that patients with CNL harboring *CSF3R*-T618I are most likely to respond to ruxolitinib, which is a reasonable therapeutic option to address spleen, symptom and disease burden in transplant ineligible patients with CNL.

Given the rarity of CNL, HSCT experience in CNL is limited. Several anecdotal case reports note long-term remission with HSCT. Although HSCT is done at all phases of the disease, maximal benefit is obtained only if patients are transplanted during the early phase of the disease. A Japanese group retrospectively analyzed the outcomes of HSCT in 14 aCML and five CNL patients transplanted between 2003 and 2014. Most were matched unrelated ($n = 14$) and received a MAC regimen. One-year OS rate was 40% in CNL, emphasizing the lack of prospective data on HSCT outcomes and the natural history of this rare MPN.[25]

FUTURE DIRECTIONS

CNL is a clinically aggressive MPN with no established standard of care treatment. The identification of CSF3R mutations has provided crucial insight into the molecular pathogenesis of CNL and has enabled avenues for therapeutic exploitation. Given the evident lack of effective management strategies in CNL, eligible patients should be considered for HSCT early on in the disease course or for enrollment in clinical trials when available. Furthermore, elucidating critical prognostic clinical and genomic markers to integrate into a validated prognostic model will inform a risk-adapted therapeutic strategy that would significantly improve outcomes in patients with CNL.

CHAPTER 73

MYELODYSPLASTIC SYNDROME/MYELOPROLIFERATIVE NEOPLASM OVERLAP SYNDROMES

Douglas Tremblay, Jonathan Feld, Nicole Kucine, Noa Rippel, Siraj M. El Jamal, and John Mascarenhas

Myelodysplastic syndrome (MDS)/myeloproliferative neoplasm (MPN) overlap syndromes are a group of rare myeloid malignancies that paradoxically exhibit both dysplastic and proliferative hematopoietic cell characteristics. They share phenotypic features of both MDS, such as dysplasia and cytopenias, and of MPNs, including constitutional symptoms, splenomegaly, and terminally differentiated blood cell expansion. There are four adult MDS/MPN overlap syndromes: chronic myelomonocytic leukemia (CMML), atypical chronic myeloid leukemia (aCML), MDS/MPN with ring sideroblasts and thrombocytosis (MDS/MPN-RS-T), and MDS/MPN unclassifiable (MDS/MPN-U). There is also a pediatric syndrome, juvenile myelomonocytic leukemia (JMML). These disorders were historically classified as either an MDS or an MPN, but in 2002, the World Health Organization (WHO) first designated MDS/MPN overlap syndromes as an independent category of tumors of hematopoietic tissues, in recognition of the unique features of these myeloid malignancies.[1] Recurrent mutations shared between the subtypes of MDS/MPNs, and the MPN and MDS highlight the interrelated nature of these diseases.

MDS/MPNs present challenges both from a diagnostic and therapeutic standpoint. As rare diseases, an accurate diagnosis can be challenging and often relies on referral to tertiary care centers with a team of experienced hematopathologists and clinicians. In addition, there is a paucity of clinical research and novel therapeutic approaches for treating these malignancies included within the MDS/MPN overlap syndromes. Treatment approaches are, therefore, largely borrowed from those used to treat MDS or the MPNs. Given advances in the molecular and pathobiologic understanding of MDS/MPNs overlap syndromes, novel therapeutic development is starting to advance, which has the potential to alter the generally poor outcomes seen with such patients.

EPIDEMIOLOGY

The epidemiology of MDS/MPN overlap syndromes is poorly described. CMML is the most common MDS/MPN overlap syndrome, with an incidence of 0.35 cases per 100,000. As expected, the incidence of CMML increases significantly with age based on SEER (Surveillance, Epidemiology, and End Results) data. There is a male predominance, and the disease is more common in those of European descent than Blacks or Asian/Pacific Islanders.

Epidemiologic data are limited for aCML, although one study suggests a slight male predominance with a median age of onset of 69 years. There is no published epidemiologic information concerning MDS/MPN-RS-T or MDS/MPN-U. JMML has an estimated incidence of 1.2 cases per million annually and accounts for approximately 2% of leukemias occurring during childhood. Males are affected more frequently than females, and approximately 50% of cases occur in infants.

DIAGNOSTIC EVALUATION AND CRITERIA

The diagnostic features for the MDS/MPN overlap syndromes, although diverse, essentially encompass a hybrid of both marrow cell dysplasia and myeloproliferation. The dysplastic features are similar to the classic features associated with MDS involving one or more of the hematopoietic lineages. The myeloproliferative component results frequently in monocytosis in CMML, thrombocytosis in MDS/MPN-RS-T, or granulocytosis in aCML. Establishing the diagnosis of a patient with an MPN/MDS overlap syndrome usually requires an integrated approach incorporating clinical presentation, laboratory data, peripheral blood and marrow morphologic evaluation, cytogenetics, and myeloid gene mutational profiling.

In general, special considerations should be taken when making the diagnosis of an MDS/MPN overlap syndrome. The diagnosis should be made prior to the patient receiving any therapy and other genetically-defined myeloid neoplasms should be excluded using cytogenetic analyses and molecular testing. In essence, MDS/MPN overlap syndromes are frequently diagnoses of exclusion.

MDS/MPN overlap syndrome patients present with abnormal blood counts with at least a single lineage cytopenia (the MDS component) or a single lineage cytosis (the MPN component). Of particular interest are the monocyte counts (associated with CMML), eosinophilia (may suggest myeloid neoplasm with *PDGFRα*, *PDGFRβ*, or *FGFR1* abnormalities), and basophilia (may suggest chronic myeloid leukemia [CML] rather than MDS/MPN overlap syndromes). Clinically, patients experience symptoms of MDS including fatigue, frequent infections, and bleeding/bruising. In addition, features of the MPNs such as constitutional symptoms and extramedullary hematopoiesis (often manifested as splenomegaly) can be observed. However, there is a wide spectrum of clinical manifestations in MDS/MPN overlap syndrome patients ranging from the patients being asymptomatic to having debilitating symptoms.

Chronic Myelomonocytic Leukemia

CMML is characterized by sustained monocytosis in the setting of bone marrow (BM) cellular dysplasia. Monocytosis is defined by having an absolute monocyte count greater than 1×10^9/L with greater than 10% monocytes being present in the white blood cell (WBC) differential count that persists for at least 3 months. An examination of the BM is critical to exclude acute myeloid leukemia (AML) from the diagnosis since CMML patients, unlike AML patients, have a blast cell percentage less than 20%. Many other entities can lead to a reactive form of monocytosis, which are discussed in detail in Chapter 49, and must be excluded. Non-neoplastic causes of monocytosis include chronic infections, autoimmune diseases, and drug reactions, among others. Other myeloid neoplasms with associated monocytosis should be excluded as well as CML, primary myelofibrosis, and MDS. The WHO diagnostic criteria for CMML are listed in Table 73.1.[1] CMML can be further subtyped based on the degree of elevation of the peripheral blood WBC count into MPN-CMML (WBC $\geq 13 \times 10^9$/L) and MDS-CMML (WBC $<13 \times 10^9$/L).

The marrow is typically hypercellular with myeloid hyperplasia and monocytosis. The dysplasia is common in the three lineages; however, dysplasia is more common and pronounced in the megakaryocyte lineage, with micromegakaryocytes and small megakaryocytes with

TABLE 73.1 **World Health Organization Diagnostic Criteria for Chronic Myelomonocytic Leukemia**

Persistent PB monocytosis $\geq 1 \times 10^9$/L, with monocytes accounting for $\geq$10% of the WBC count
Not meeting WHO criteria for *BCR-ABL1*$^+$ CML, PMF, PV, or ET[a]
No evidence of *PDGFRA*, *PDGFRB*, or *FGFR1* rearrangement or *PCM1-JAK2* (should be specifically excluded in cases with eosinophilia)
<20% blasts in the blood and BM[b]
Dysplasia in 1 or more myeloid lineages. If myelodysplasia is absent or minimal, the diagnosis of CMML may still be made if the other requirements are met and
An acquired clonal cytogenetic or molecular genetic abnormality is present in hemopoietic cells[c]
or
The monocytosis (as previously defined) has persisted for at least 3 months and
All other causes of monocytosis have been excluded

[a] Cases of MPN can be associated with monocytosis or they can develop it during the course of the disease. These cases may simulate CMML. In these rare instances, a previous documented history of MPN excludes CMML, whereas the presence of MPN features in the BM and/or of MPN-associated mutations (*JAK2, CALR*, or *MPL*) tend to support MPN with monocytosis rather than CMML.

[b] Blasts and blast equivalents include myeloblasts, monoblasts, and promonocytes. Promonocytes are monocytic precursors with abundant light gray or slightly basophilic cytoplasm with a few scattered, fine lilac-colored granules, finely distributed, stippled nuclear chromatin, variably prominent nucleoli, and delicate nuclear folding or creasing. Abnormal monocytes, which can be present both in the PB and BM, are excluded from the blast count.

[c] The presence of mutations in genes often associated with CMML (e.g., *TET2*, *SRSF2*, *ASXL1*, *SETBP1*) in the proper clinical context can be used to support a diagnosis. It should be noted, however, that many of these mutations can be age-related or be present in subclones. Therefore, caution would have to be used in the interpretation of these genetic results.

BM, Bone marrow; *CML*, chronic myeloid leukemia; *CMML*, chronic myelomonocytic leukemia; *ET*, essential thrombocythemia; *MPN*, myeloproliferative neoplasm; *PB*, peripheral blood; *PMF*, primary myelofibrosis; *PV*, polycythemia vera; *WBC*, white blood cell; *WHO*, World Health Organization.

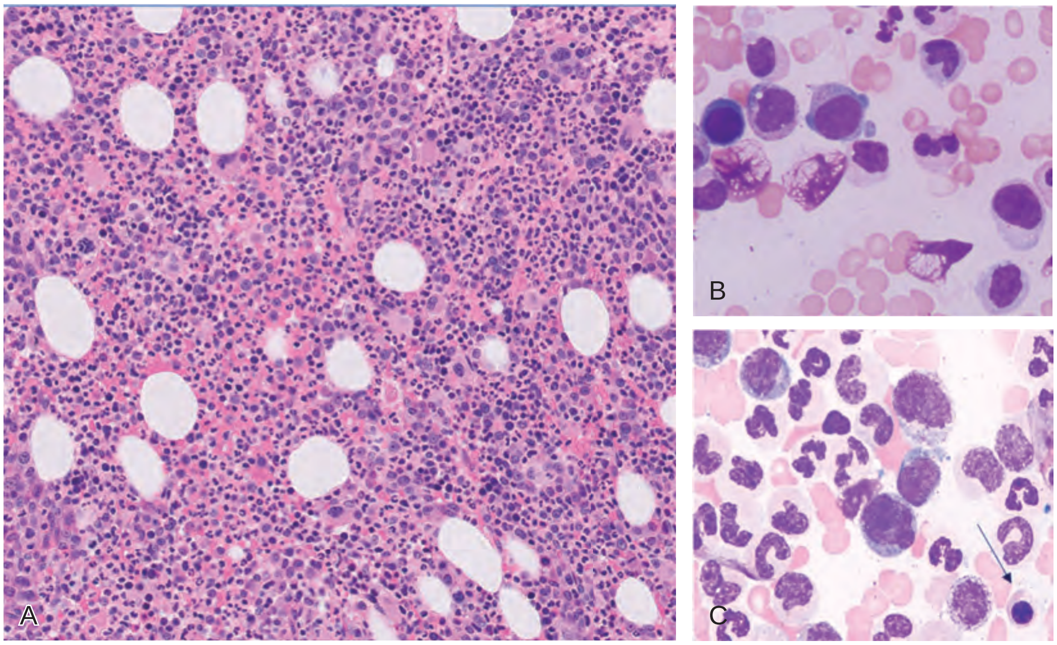

Figure 73.1 CHRONIC MYELOMONOCYTIC LEUKEMIA MORPHOLOGICAL FINDINGS. (A) Bone marrow (BM) biopsy shows hypercellular marrow with myeloid hyperplasia and dysplastic megakaryocytes. (B) Peripheral blood (PB) shows atypical granulocytes and monocytes. (C) BM smears show the myeloid hyperplasia with hypogranular and atypical forms, note the erythroid precursor with megaloblastoid changes *(arrow)*.

hypolobated nuclei being a prominent feature (Fig. 73.1). In rare cases where the dysplasia may not be overt, the diagnosis of CMML can be made if a cytogenetic or myeloid mutational abnormality is detected or if the monocytosis is persistent with no secondary causes identified. Mild BM fibrosis is not uncommon in CMML.

A plasmacytoid dendritic cell (PDC) proliferation (CD123-positive) is a feature of CMML that is observed in 20% of cases but is a non-specific finding and can be seen in other myeloid neoplasms. Of note, CMML is the most common myeloid neoplasm that is associated with systemic mastocytosis (see Chapter 75).

Recently, an entity termed “oligomonocytic chronic myelomonocytic leukemia” has been described. This condition is characterized by blood monocytes $\geq$10% of the WBC without an absolute monocyte count greater than 1×10^9/L. These patients, when compared to CMML, are typically younger and have lower WBCs and absolute neutrophils counts. The molecular signature is similar to CMML with mutations in *ASXL1, TET2*, and *SRSF2*. Progression to overt CMML occurs in approximately 40% of cases over a median time of 12 months. Thus, these cases should not be classified as a type of MDS but rather to represent a forme fruste of CMML.

TABLE 73.2 World Health Organization Diagnostic Criteria for Atypical Chronic Myeloid Leukemia

- Peripheral blood leukocytosis (WBC count ≥13 × 10^9/L) because of increased numbers of neutrophils and their precursors with prominent dysgranulopoiesis
- Neutrophil precursors (promyelocytes, myelocytes, metamyelocytes) ≥10% of leukocytes
- No Ph chromosome or *BCR-ABL1* fusion gene and not meeting criteria for PV, ET, or PMF[a]
- No evidence of *PDGFRA*, *PDGFRB*, *FGFR1* rearrangement, or *PCM1-JAK2*
- Minimal absolute basophilia; basophils usually <2% of leukocytes
- No or minimal absolute monocytosis; monocytes usually <10% of leukocytes
- Hypercellular bone marrow with granulocytic proliferation and granulocytic dysplasia, with or without dysplasia in the erythroid and megakaryocytic lineages
- Less than 20% blasts in the blood and bone marrow

[a] Cases of myeloproliferative neoplasm *(MPN)*, particularly those in accelerated phase and/or in postpolycythemic or postessential thrombocythemic myelofibrosis, if neutrophilic, may simulate aCML. A previous history of MPN, the presence of MPN features in the bone marrow, and/or MPN-associated mutations (in *JAK2*, *CALR*, or *MPL*) tend to exclude a diagnosis of aCML. Conversely, a diagnosis of aCML is supported by the presence of *SETBP1* and/or *ETNK1* mutations. The presence of a *CSF3R* mutation is uncommon in aCML and, if detected, should prompt a careful morphologic review to exclude an alternative diagnosis of chronic neutrophilic leukemia or other myeloid neoplasm.

aCML, Atypical chronic myeloid leukemia; *ET*, essential thrombocythemia; *Ph*, Philadelphia; *PMF*, primary myelofibrosis; *PV*, polycythemia vera; *WBC*, white blood cell; *WHO*, World Health Organization. Adapted from Arber DA, Orazi A, Hasserjian R, et al. The 2016 revision to the World Health Organization classification of myeloid neoplasms and acute leukemia. *Blood*. 2016;127(20):2391–2405.

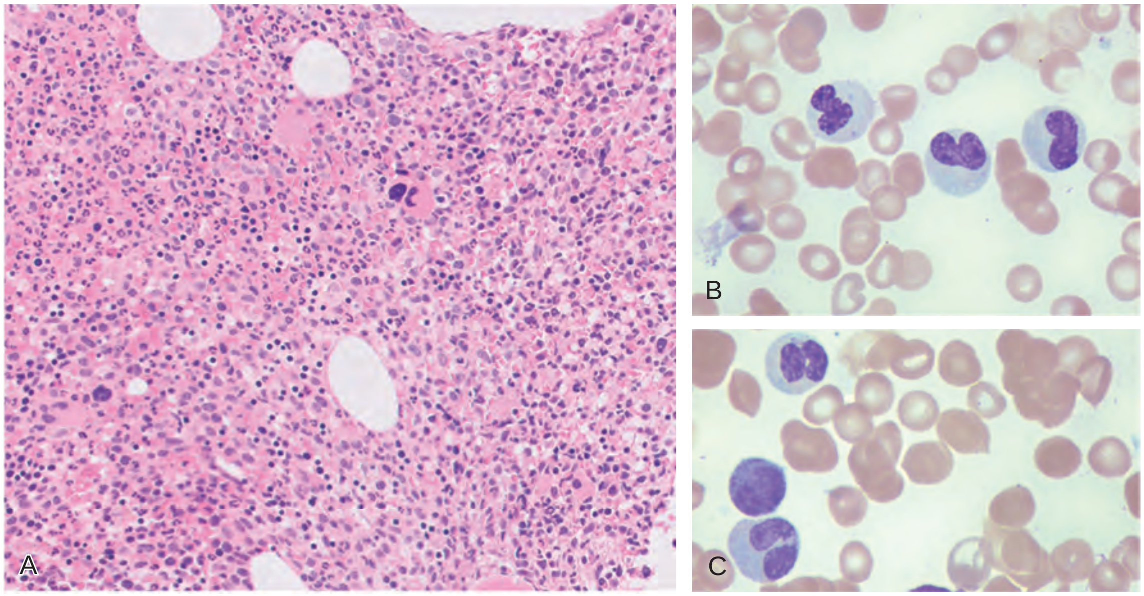

Figure 73.2 ATYPICAL CHRONIC MYELOID LEUKEMIA. (A) Bone marrow (BM) biopsy shows hypercellular marrow with myeloid hyperplasia. The megakaryocytes are morphologically normal. (B and C) The dysplastic features are limited to the granulocytic lineage as seen here.

Atypical Chronic Myeloid Leukemia

aCML is defined by left-shifted neutrophilic leukocytosis with severe dysgranulopoiesis and greater than 10% immature myeloid precursor cells present in the peripheral blood. Anemia and thrombocytopenia are common. These patients lack the *BCR-ABL-1* fusion protein that is diagnostic of CML (see Chapter 69). Basophilia and eosinophilia are not typical features of aCML and should prompt careful consideration of a diagnosis of another myeloid neoplasm. aCML often presents with extramedullary disease, especially in the spleen and liver. The two other diagnoses that resemble aCML and should be ruled out are CMML (which exhibits monocytosis) and CML (which is *BCR-ABL-1*-positive). The WHO diagnostic criteria for aCML are listed in Table 73.2.

The BM in aCML is hypercellular with myeloid hyperplasia and a high myeloid-to-erythroid (M:E) (Fig. 73.2). aCML is characterized by dysplastic hematopoiesis and the presence of immature myeloid precursor cells in the peripheral blood that distinguishes it from chronic neutrophilic leukemia (CNL) (see Chapter 72). In addition to the granulocytic dysplasia, erythroid and megakaryocytic dysplasia are also common. Importantly, aCML is characteristically associated with mutations in *SETBP1* and/or *ETKN1*. Since the *CSF3R* mutation is seen in less than 10% of patients with aCML, the presence of this mutation, in conjunction with the absence of BM dysplasia and immature myeloid precursors, suggests a diagnosis of CNL rather than aCML. The presence of MPN mutations involving *JAK2*, *MPL*, or *CALR* tends to exclude the diagnosis of aCML

Myelodysplastic/Myeloproliferative Syndrome With Ring Sideroblasts and Thrombocytosis

Patients with MDS/MPN-RS-T can present with vasomotor symptoms, such as migraine headaches, erythromelalgia, and paresthesias, or can have fatigue related to anemia. Additionally, some patients initially present incidentally after routine laboratory testing that reveals thrombocytosis and anemia. Table 73.3 lists the WHO diagnostic criteria for MDS/MPN-RS-T,[1] which includes refractory anemia, ≥15% ring sideroblasts in the BM, and thrombocytosis. The presence of the spliceosome mutation *SF3B1* co-mutated with an MPN driver mutation (in particular *JAK2V617F*) is highly suggestive of MDS/MPN-RS-T in the appropriate clinical setting.[2] Distinction between MDS with ring sideroblasts is essential, which in contrast to MDS/MPN-RS-T, lacks thrombocytosis and has hypolobulated, instead of hyperlobulated, atypical megakaryocytes (Fig. 73.3). Other non-clonal disorders can result in the appearance of ring sideroblasts including lead or zinc toxicity, copper or pyridoxine deficiency, the use of particular medications (linezolid, isoniazid), excessive alcohol use, and congenital forms of sideroblastic anemias (see Chapter 39). Reactive causes of thrombocytosis, including infection, rheumatologic conditions, recent trauma/surgery, blood loss, iron deficiency, and hemolysis, should be ruled out (see Chapters 29 and 71).

TABLE 73.3 World Health Organization Diagnostic Criteria for Myelodysplastic Syndrome/Myeloproliferative Neoplasm With Ring Sideroblasts and Thrombocytosis

- Anemia associated with erythroid lineage dysplasia with or without multilineage dysplasia, ≥ 15% ring sideroblasts,[a] <1% blasts in PB, and <5% blasts in the BM
- Persistent thrombocytosis with platelet count ≥450 × 10^9/L
- Presence of an *SF3B1* mutation or, in the absence of *SF3B1* mutation, no history of recent cytotoxic or growth factor therapy that could explain the myelodysplastic/myeloproliferative features[b]
- No *BCR-ABL1* fusion gene, no rearrangement of *PDGFRA*, *PDGFRB*, or *FGFR1*; or *PCM1-JAK2*; no (3;3)(q21;q26), inv(3)(q21q26) or del(5q)[c]
- No preceding history of MPN, MDS (except MDS-RS), or other type of MDS/MPN

[a] At least 15% ring sideroblasts are required even if *SF3B1* mutation is detected.
[b] A diagnosis of MDS/MPN-RS-T is strongly supported by the presence of *SF3B1* mutation together with a mutation in *JAK2* V617F, *CALR*, or MDS-RS, myelodysplastic syndrome with ring sideroblasts; *MPL* genes.
[c] In a case which otherwise fulfills the diagnostic criteria for MDS with isolated del(5q)-no or minimal absolute basophilia; basophils usually less than 2% of leukocytes.

BM, Bone marrow; *MDS*, myelodysplastic syndrome; *MDS-RS*, myelodysplastic syndrome with ring sideroblasts; *MPN*, myeloproliferative neoplasm; *MPN-RS-T*, myeloproliferative neoplasm with ring sideroblasts and thrombocytosis; *PB*, peripheral blood.

GENERAL DIAGNOSTIC APPROACH

MDS/MPN overlap syndromes should be suspected in patients who display phenotypic properties of both bone marrow failure and myeloproliferation. Fig. 73.4 summarizes the diagnostic approach for patients with MDS/MPN overlap syndromes. As noted in the WHO diagnostic criteria (Tables 73.1–73.4), a bone marrow biopsy is essential for the diagnosis of MDS/MPN overlap syndromes in order to distinguish among the diagnoses and from other myeloid malignancies and to determine the type of MDS/MPN overlap syndrome. Histopathology review by an expert hematopathologist is key for proper diagnosis.

In all MDS/MPN overlap syndrome patients, exclusion of chronic myeloid leukemia *(CML)* with polymerase chain reaction (PCR) for *BCR-ABL1* must be performed. CMML, the most common MDS/MPN, can be diagnostically challenging given that monocytosis is seen in other related hematologic disorders or can be reactive due to chronic infections, autoimmune disorders, or other systemic inflammatory processes. Therefore, persistent monocytosis lasting more than 3 months must be documented, unless there is a clonal cytogenetic or molecular marker specific for myeloid malignancies, such *TET2*, *SRSF2*, *ASXL1*, or *SETBP1*. The diagnosis of aCML should be considered in a patient with neutrophilia with greater than 10% immature myeloid cells being the differentiating feature among other MDS/MPN overlap syndromes. Careful consideration of CNL must also be given when considering a diagnosis of aCML given that both have a high frequency of the *CSF3R* mutation. Among the differentiating features, the presence of ≥10% immature granulocytes strongly favors aCML and the presence of less than 10% with greater than 80% neutrophils and bands favors CNL. MDS/MPN-RS-T is characterized by thrombocytosis, concurrent anemia, and ring sideroblasts which differentiates this diagnosis from ET. Cases that harbor features of both MDS and MPN but do not meet WHO diagnostic criteria for any MDS/MPN subtype can be categorized in the “grab-bag” category of MDS/MPN-U.

MDS/MPN-U

Figure 73.4 DIAGNOSTIC ALGORITHM FOR DIAGNOSIS OF PATIENTS WITH AN MYELODYSPLASTIC SYNDROME/MYELOPROLIFERATIVE NEOPLASM OVERLAP SYNDROME. Patients with both dysplasia and myeloproliferative features should be evaluated for the presence of monocytosis, thrombocytosis, and neutrophilia. Patients who do not meet the criteria for specific myelodysplastic syndrome *(MDS)*/myeloproliferative neoplasm *(MPN)* subtypes can be diagnosed with the catch-all diagnosis of MDS/myeloproliferative neoplasm unclassifiable (MPN-U). *aCML*, Atypical chronic myeloid leukemia; *CMML*, chronic myelomonocytic leukemia; *MPN-RS-T*, myeloproliferative neoplasm with ring sideroblasts and thrombocytosis.

Myelodysplastic/Myeloproliferative Syndrome, Unclassifiable

MDS/MPN-U is, by definition, a diagnosis of exclusion, and the clinical presentation varies widely. By definition, MDS/MPN-U is characterized by at least one dysplastic lineage, less than 20% blasts in the marrow and/or peripheral blood, and absence of *BCR-ABL-1* (which defines CML) and the fusions genes involving *PDGFRA, PDGFRB*, and *FGFR1* (which define eosinophilia-associated myeloid/lymphoid neoplasms). In addition, there must be dysplastic and proliferative features that do not meet the diagnostic criteria for CMML, JMML, aCML, or MDS/MPN-RS-T U. This "wastebasket" category of MDS/MPN overlap syndromes can include patients who will eventually evolve to a definitive MPN/MDS overlap syndrome or a rare form of an MPN that is associated with dysplastic changes without documentation of a prior chronic phase.

The mutational landscape of MDS/MPN-U is heterogeneous, with *ASXL1* being the most commonly mutated gene followed by *TET2* and *SRSF2*. *JAK2* mutations can be seen in up to 30% of patients with MDS/MPN-U, while this mutation is rare in MDS. The presence of a *JAK2* mutation in the setting of dysplasia without features of the other MDS/MPN overlap syndromes strongly suggests a diagnosis of MDS/MPN-U. However, cases of MDS with isolated del(5q) may be associated with a *JAK2* mutation and are better classified as MDS with isolated del(5q) and concurrent *JAKV617F* rather than MDS/MPN-U. In comparison to other MDS/MPN overlap syndrome diagnostic categories with strict definitions, the diagnostic criteria for MDS/MPN-U are poorly defined and therefore misclassification is common. Therefore, consultation with an expert hematopathologist is essential for the proper diagnosis of MDS/MPN-U (Fig. 73.4).

Juvenile Myelomonocytic Leukemia

JMML is a rare MPN/MDS overlap syndrome that occurs almost exclusively in infants and young children. It is characterized by an aggressive clinical course, with monocytic and granulocytic proliferation, organ infiltration with significant splenomegaly, and activating mutations in the Ras/Erk pathway (Fig. 73.5). Ras signaling proteins are small guanosine triphosphatase (GTPase) molecules that are ubiquitously expressed. They play diverse cellular roles including regulation of proliferation, survival, and differentiation. Ras pathway activation stimulates a number of signaling pathways including Raf/MEK/ERK and PI3K/AKT/mTOR. Mutations in *PTPN11, NRAS, KRAS, CBL, or NF1* account for approximately 90% of JMML cases. These canonical Ras mutations are associated with five clinically and biologically distinct subtypes of JMML. Germline mutations in Ras family genes, so-called RASopathies, are a clinically distinct group of genetic syndromes that are described below.

PTPN11 is the most common mutation found in JMML, encompassing approximately 40% of all cases. The *PTPN11* gene encodes a cytoplasmic protein tyrosine phosphatase SHP-2, a dual-specificity phosphatase, which contains two tandem SH-2 domains at the N-terminus and a catalytic PTP domain at the C-terminus. All *PTPN11* genes are gain-of-function, missense mutations resulting in constitutive Ras activation. *PTPN11*-associated JMML is associated with an older age at presentation and a more aggressive course. Noonan syndrome is an autosomal-dominant condition associated with a germline *PTPN11* mutation in approximately 50% of patients that causes abnormal development of multiple organs. Most individuals with Noonan syndrome have normal intelligence, but some may have special educational needs or intellectual disability. Noonan syndrome occurs in about 1 in 2500 births and is clinically associated with short stature, facial dysmorphism, neurodevelopmental problems, and lymphedema. Congenital heart disease is present in 80% of patients with Noonan syndrome, most frequently pulmonary stenosis, although atrial septal defects, and hypertrophic cardiomyopathy can also be seen. Cardiac manifestations usually present within the first year of life.[3] Noonan syndrome can be associated with a transient myeloproliferative disorder that is more indolent than JMML but in some cases can progress to JMML (more commonly with certain *PTPN11* or *KRAS* mutations). The *PTPN11*-associated MPN can be present at birth or develop during infancy or childhood.

NRAS and *KRAS* mutations are heterozygous somatic RAS mutations that lock RAS into the active guanosine triphosphate-bound state, thereby diminishing GTPase activity. *NRAS or KRAS* mutations are present in approximately 25% of JMML cases. A small proportion of patients with Noonan syndrome will harbor a mutation in *NRAS* or *KRAS*, with the latter associated with more severe intellectual

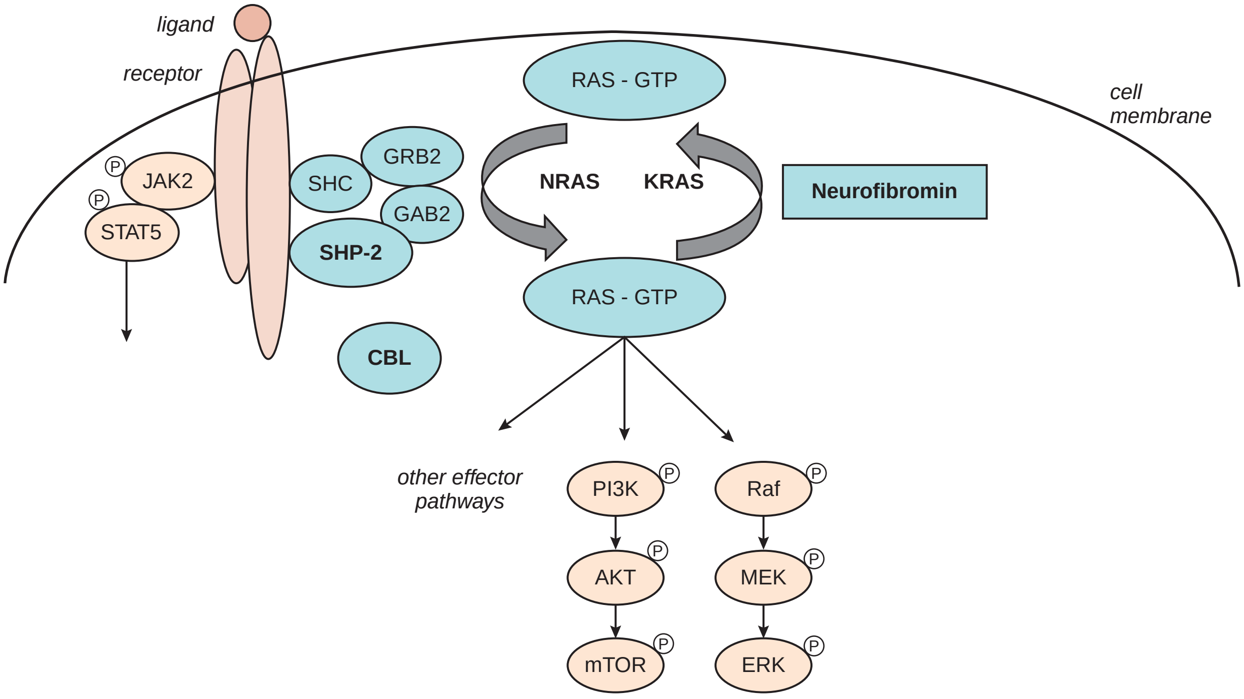

Figure 73.5 RAS PATHWAY WITH MUTATIONS IN JUVENILE MYELOMONOCYTIC LEUKEMIA. Mutations that are recurrently mutated are highlighted in bold. *(Adapted from Niemeyer CM. JMML genomics and decisions. Hematology Am Soc Hematol Educ Prog. 2018;2018[1]:307–312.)*

disability. *NRAS*-mutated JMML has a highly varied clinical presentation and course, with some young infants experiencing an indolent course with spontaneous hematologic improvement being observed during a 2- to 4-year follow-up period. By contrast, *KRAS*-mutated disease is a particularly aggressive form of JMML.

CBL encodes a member of the Cbl family of proteins, which functions as an E3 ubiquitin ligase. CBL syndrome is an autosomal-dominant developmental disorder resulting from germline missense *CBL* mutations, which are characterized by impaired growth, developmental delay, cryptorchidism, vasculitis, and a predisposition to develop JMML. *CBL* mutations account for approximately 15% of cases of JMML. Many individuals with CBL syndrome experience spontaneous regression of their JMML. Importantly, JMML specimens from affected children are characterized by loss of the normal CBL allele through acquired isodisomy.

NF1, located on chromosome 17q11.2, encodes neurofibromin, a GTP-ase activating protein that acts as a negative modulator of RAS function. Loss of a normal *NF1* allele in leukemic cells therefore results in RAS hyperactivity. The syndrome characterized by *NF1* mutations, neurofibromatosis 1 (NF1), is an autosomal-dominant disorder clinically characterized by café-au-lait macules, iris hamartomas (Lisch nodules), axillary and inguinal freckling, and neurofibromas. Germline loss-of-function mutations in NF1 are the molecular cause for neurofibromatosis type 1 is a so-called "cancer predisposition syndrome." Additional tumors, including optic gliomas and soft tissue sarcomas, appear after the first year of life. Although these signs and symptoms are often present, children carrying germline NF1 mutations have a high likelihood of developing JMML, and JMML may, in some cases, actually be the presenting phenotype (without the presence of the aforementioned skin changes) that highlights the importance of *NF1* and hyperactive RAS signaling in normal myeloid cell growth and leukemogenesis.[4,5] *NF-1* mutated JMML encompasses approximately 10% of JMML cases and is clinically characterized by higher platelet counts, higher marrow blast percentages, and older age at diagnosis as compared with other JMML subtypes.

It is important to distinguish germline versus somatic mutations given that germline mutations can be associated with MPNs that are transient and may resolve spontaneously. Searching for the characteristic mutations in non-hematopoietic tissues (such as fibroblasts) can determine the germline versus somatic nature of a RAS pathway mutation.

TABLE 73.4 World Health Organization Diagnostic Criteria for Juvenile Myelomonocytic Leukemia

I Clinical and hematologic features (all 4 features mandatory)
• PB monocyte count ≥1 × 10^9/L
• Blast percentage in PB and BM <20%
• Splenomegaly
• Absence of Philadelphia chromosome (*BCR/ABL1* rearrangement)
II Genetic studies (1 finding sufficient)
• Somatic mutation in *PTPN11*[a] or *KRAS*[a] or *NRAS*[a]
• Clinical diagnosis of NF1 or *NF1* mutation
• Germ line *CBL* mutation and loss of heterozygosity of CBL[b]
III For patients without genetic features, besides the clinical and hematologic features listed under I, the following criteria must be fulfilled:
• Monosomy 7 or any other chromosomal abnormality or at least 2 of the following criteria:
• Hemoglobin F increased for age
• Myeloid or erythroid precursors on PB smear
• GM-CSF hypersensitivity in colony assay
• Hyperphosphorylation of STAT5

[a] Germ line mutations (indicating Noonan syndrome) need to be excluded.
[b] Occasional cases with heterozygous splice site mutations.
BM, Bone marrow; NF1, neurofibromatosis 1; *PB*, peripheral blood.
From Locatelli F, Niemeyer CM. How I treat juvenile myelomonocytic leukemia. *Blood.* 2015;125(7):1083–1090.

The diagnostic criteria for JMML (Table 73.4) include a combination of clinical, hematologic, and genetic features. Patients must have an elevated peripheral monocyte count over 1 × 10^9/L, blast numbers in the BM and peripheral blood below 20%, splenomegaly, and the absence of a *BCR-ABL1* rearrangement. In addition to these features, a genetic mutation is required (a somatic mutation in *PTPN11*, *KRAS*, or *NRAS*, a germline mutation in *CBL* or loss of heterozygosity of *CBL*, or a diagnosis of neurofibromatosis type 1 or a mutation in *NF1*). In patients without somatic mutations, a combination of other features is needed to establish a diagnosis, such as monosomy 7, or other chromosomal abnormalities in addition to an elevated hemoglobin F level for the patient's age, myeloid or erythroid precursors observed on the peripheral smear, *in vitro* hypersensitivity of hematopoietic progenitor cells to granulocyte-macrophage colony-stimulating factor (GM-CSF), or hyperphosphorylation of STAT5.[1]

Children presenting with JMML are often quite ill and present with disease features secondary to marrow and organ infiltration. Common presenting symptoms include fevers, failure to thrive, and splenomegaly. Hepatomegaly may also be present, and lung involvement due to leukemic infiltration manifesting as cough and dyspnea, with abnormal findings on chest X-ray, is possible. Blood tests frequently show leukocytosis with monocytosis, and thrombocytopenia. A small population of blasts may be seen in the peripheral blood.

PATHOGENESIS AND MOLECULAR CHARACTERIZATION

Shared Pathogenic Mechanisms

Despite clinical differences, the MDS/MPN overlap syndromes share a multistep pathogenesis, with alterations initially in genes typically associated with MDS, followed by additional mutations characteristic of other gene classes. Commonly mutated genes in MDS/MPNs include those involved in epigenetic regulation, transcriptional regulation, post-transcriptional modulation (in the form of splicesome mutations), and signaling pathways such as JAK-STAT. Notably, mutations in *TP53*, while common in MDS and AML, are very rare in these patients, although they can be seen in up to 10% of MDS/MPN-U patients. Fig. 73.6 demonstrates the frequency of specific mutations in adult MDS/MPN overlap syndrome subtypes based on a study of 367 patients where 30 genes were recurrently mutated in ≥3% of patients. Among all MDS/MPN overlap syndrome patients, the most common mutated genes were *ASXL1* (51%), *TET2* (45%), *SRSF2* (35%), *SF3B1* (24%), *JAK2* (19%), *EZH2* (17%), *RUNX1* (17%), *SETBP1* (15%), *NRAS* (13%), *CBL* (13%), and *KRAS* (10%). Of note, patients with MDS/MPN-RS-T had a lower mean number of variants per patient compared with other MDS/MPN overlap syndrome subtypes. Certain mutations are highly enriched in different subtypes. For example, *SF3B1* mutations are found in nearly all patients with MDS/MPN-RS-T and *ASXL1* is identified in nearly all patients with aCML.[6]

As described, monocytosis is the hallmark of both CMML and JMML. Interestingly, the two diseases usually reach a similar phenotype via different genetic mechanisms. A pre-disease CMML state is thought to occur when initiating mutations are acquired, most frequently in *TET2*, *SRSF2*, *ASXL1*, or the Ras pathway associated genes. These mutations favor increased monocyte-precursors and monocyte production in the BM. However, the disease only presents itself after an additional second-hit mutation occurs. Mutations in the Ras pathway typify MPN-CMML, a more proliferative subtype of CMML, while additional MDS-associated mutations usually result in dysplasia and MDS-CMML phenotype.

Interestingly, deletion of *TET2* in murine models leads to an increased Lin−Sca-1+c-Kit+ (LSK) cell pool. These cells have an increased hematopoietic repopulating capacity and abnormal cell differentiation pattern that skews heavily toward monocytic/granulocytic lineages. These mice develop a myeloid malignancy resembling CMML, suggesting that *TET2* functions as a tumor suppressor to regulate hematopoietic stem cell (HSC) differentiation.

JMML is characterized by either germline or somatic mutations in the Ras pathway, as previously described. Germline mutations (i.e., RASopathies) in NF1 (*NF1* germline mutation), Noonan syndrome (*PTPN11, NRAS*, or *KRAS* germline mutations), or CBL syndrome (*CBL1* germline mutation) often have different functional effects. The *PTPN11* mutations that are germline have a weaker gain-of-function effect as compared with somatically acquired mutations. Interestingly, some somatically acquired Ras mutations can occur very early in life, even in utero. In a study of patients who developed JMML at ages 2 to 19, sequencing of dried blood from Guthrie cards taken at birth detected acquired mutations in *PTPN11*, *NRAS*, and *KRAS*, suggesting that the JMML clone originated in utero in these children.

Importantly, mutations in the RASopathy genes (*PTPN11, NRAS, KRAS, CBL, and NF1*) are mutually exclusive within a given patient, implying that a mutation in any of these genes is sufficient

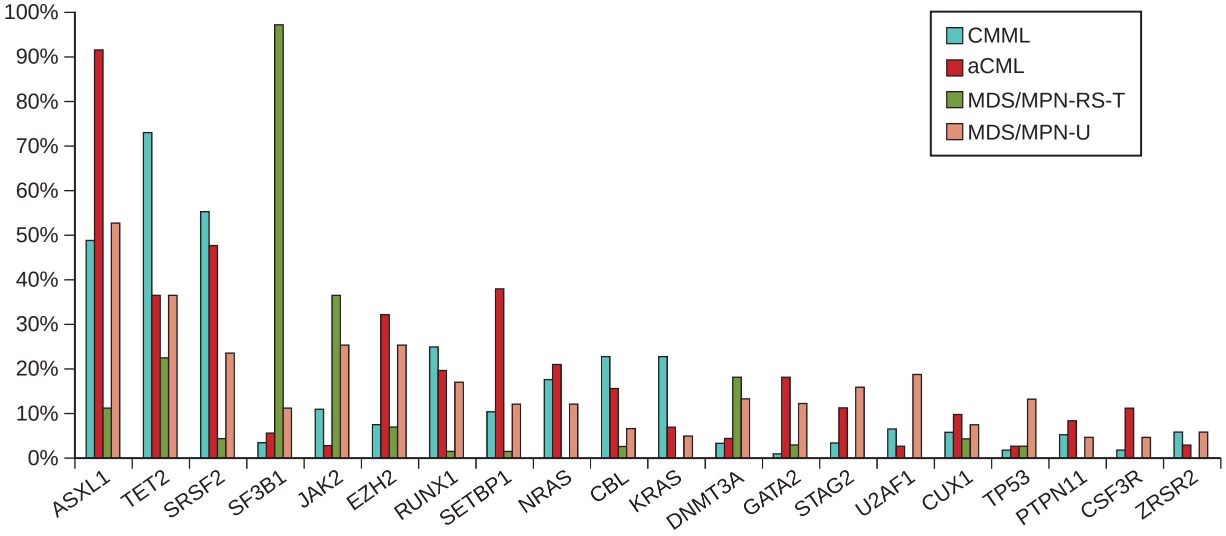

Figure 73.6 DISTRIBUTION OF SOMATIC MUTATIONS IN A SERIES OF 367 MYELODYSPLASTIC SYNDROME/MYELOPROLIFERATIVE NEOPLASM PATIENTS. The distribution that differed among different subtypes, although many genes are recurrent mutated across disease categories. *aCML*, Atypical chronic myeloid leukemia; *CMML*, chronic myelomonocytic leukemia; *MDS*, myelodysplastic syndrome; *MPN-RS-T*, myeloproliferative neoplasm with ring sideroblasts and thrombocytosis; *MPN-U*, myeloproliferative neoplasm unclassifiable. *(Adapted from Palomo L, Meggendorfer M, Hutter S, et al. Molecular landscape and clonal architecture of adult myelodysplastic/myeloproliferative neoplasms. Blood. 2020;136[16]:1851–1862.)*

to drive the JMML disease phenotype. In patients who lack one of these five Ras pathway mutations, there may be abnormal Ras signaling in the BM microenvironment that can result in JMML. For instance, a murine model where *PTPN11* mutation is present in the BM stroma cells, and not hematopoietic cells, results in a phenotype that is indistinguishable from JMML where *PTPN11* is present in hematopoietic cells.

Recently, the origin of the leukemia stem cell (LSC) in JMML has been studied by Louka et al. using primary patient specimens, FACS, and single-cell RNA sequencing revealed that the LSC is markedly heterogeneous in origin. Specifically, the granulocyte monocyte progenitors (GMP, Lin-CD34+CD38-CD90+CD45RA-) and a novel double-positive cell population (Lin-CD34+CD38-CD90+CD45RA+) were aberrantly increased in JMML samples as compared with healthy pediatric controls. Using an in vivo xenotransplantation model, the authors demonstrated that the LSC resided within the JMML HSC compartment, in addition to the GMP and the novel double-positive cell population. Single-cell index sorting of Lin-CD34+ stem cell followed by colony genotyping demonstrated that the JMML HSCs and progenitor cells contain clonally dominant RAS pathway mutations, as well as subclones with additional canonical myeloid mutations such as *ASXL1*, *SETBP1*, and monosomy 7.[7] They proposed model for LSC clonal evolution in JMML that proposes that "first hit "occurs within the RAS pathway, followed later by additional hits leading to a phenotypically heterogeneous HSC pool (Fig. 73.7).[8]

MDS/MPN-RS-T is thought to develop in a similar fashion as MDS-RS, with mutations in *SF3B1* occurring initially, as 85% to 95% of patients with this disease entity harbor this mutation. A second mutation, most commonly *JAK2V617F*, is then required to convert the MDS-RS into the MDS/MPN-RS-T phenotype. aCML and MDS/MPN-U do not appear to closely follow the above pathogenic paradigm, with the later disease especially difficult to define due to its heterogeneity. A study to evaluate the genetic signatures of the different MDS/MPN subsets from a large and diverse cohort of 177 adult MDS/MPN overlap syndrome patients revealed similarities between aCML and CMML, with MDS/MPN-RS-T having a distinct transcriptome, and MDS/MPN-U showing features of both disorders.[9] In another large study of 367 adult patients with MDS/MPN overlap syndrome that utilized genome-wide sequencing, the authors were able to reclassify MDS/MPN-U cases into molecular subtypes that resembled other MDS/MPN overlap syndromes. For instance, a co-mutation in *SRSF2* with either *TET2* or *RUNX1* were termed CMML-like and had similar hematologic parameters as pathologically defined CMML (i.e., monocytosis). Similarly, co-mutation of *ASXL1* and *SETBP1* in MDS/MPN-U patients displayed hematologic features similar to aCML, and the presence of *SF3B1* and *JAK2*-mutations resembled MDS/MPN-RS-T, with a higher percentage of ringed sideroblasts and an excellent prognosis. Overall, 61% of all MDS/MPN-U cases in this study could be genomically reclassified as another MDS/MPN overlap syndrome subtype even though they did not meet the standard pathologic diagnostic criteria. This study highlights that genomic features can be useful in reclassifying pathologically ambiguous cases of MDS/MPN-U.[6]

Epigenetic/Transcription Factor Mutations

Epigenetic regulatory genes are recurrently mutated in the various MDS/MPN overlap syndromes. *DNMT3A*, *ASXL1*, *TET2*, and *EZH2* are the most commonly mutated epigenetic genes in MDS/MPN overlap syndromes, while *RUNX1* is the most frequently mutated transcription factor. *ASXL1* is perhaps the most commonly and widely mutated gene in cases with an MDS/MPN overlap syndrome and can be found in the majority of patients with aCML, CMML, and MDS/MPN-RS-T. *TET2* mutations can be seen in each type of MDS/MPN overlap syndrome but are most common in CMML. *EZH2* mutations are most frequently identified with aCML and MDS/MPN-U. Mutations in *RUNX1* are most common in aCML. *DNMT3A* mutations are rare, though occasionally seen in MDS/MPN-RS-T. The above gene mutations have prognostic implications. *ASXL1* universally portends a poor prognosis across the spectrum of adult MDS/MPN overlap syndromes, while outcomes are worse with *TET2* mutations in aCML, *RUNX1* mutations in CMML and aCML, and *EZH2* mutations in MDS/MPN-RS-T and MDS/MPN-U.[10]

SETBP1 is a DNA-binding protein that forms part of a group of proteins that act together to affect histone methylation, making chromatin more accessible and thereby regulating gene expression. *SETBP1* mutations are observed in each of the MDS/MPN overlap syndromes but most commonly in aCML and least frequently in JMML. *SETBP1* alterations are gain-of-function mutations frequently associated with advanced age and monosomy 7/deletion 7q (−7/del(7q)). This mutation is associated with a poor prognosis and higher risk of leukemic transformation in JMML, CMML, and MDS/MPN-RS-T patients.

In JMML, aberrant DNA methylation is also a prominent pathogenic feature. Specifically, there is frequent hypermethylation of four specific CpG gene islands (*BMP4, CALCA, CDKN2B*, and *RARB*). Interestingly, this methylation status can be classified as high, intermediate, and low. This classification correlates with survival and relapse after allogeneic HSC transplant (alloSCT), with higher methylation status patients having a 42% 5-year survival in contrast to 72% in the low methylation group. After multivariable analysis, DNA methylation status retained independent prognostic significance. Aberrant

Figure 73.7 Proposed model of hematopoietic stem cells *(HSC)* clonal evolution in juvenile myelomonocytic leukemia, with clonally dominant RAS pathway mutations occurring first followed by mutations in canonical myeloid mutations, such as *ASXL1, SETPB1*, and monosomy 7, occurring later and resulting in a phenotypically heterogeneous hematopoietic stem cell pool. *(Adapted from Sundaravel S, Steidl U. Stem cell origins of JMML. J Exp Med. 2021;218[2]:e20202152.)*

methylation also appears to be specific for JMML leukemic cell progeny and represents an early pathogenetic event.

Spliceosome Mutations

The spliceosome apparatus is a large ribonucleoprotein (RNP) complex of 100+ proteins and 5 small nuclear proteins that is responsible for the removal of introns from pre-mRNA and preparation of mRNA for protein expression. Thus, mutations in these genes can lead to aberrant protein expression. It is currently hypothesized that less than 20% of spliced proteins are affected by spliceosome mutations, with disease due to gain or loss of functional splicing of targeted oncogenes or tumor suppressor genes, respectively. The most common splicing gene mutations in myeloid malignancies occur in the *SF3B1*, *SRSF2*, *U2AF1*, and *ZRSR2* genes. *SRSF2* is most commonly mutated in CMML, aCML, and MDS/MPN-U; its role in determining patient prognosis in these diseases, especially CMML, is controversial. As previously discussed, *SF3B1* occurs in up to 90% of MDS/MPN-RS-T. *U2AF1* is associated with a worse overall survival (OS), and *ZRSR2* mutations are most common in CMML. Spliceosome mutations are extremely rare in JMML.

Cell Signaling Gene Mutations

Genes mutated in cell signaling pathways typically promote proliferative changes. Recurrently mutated genes in MDS/MPN overlap syndromes include those in the Ras pathway and MPN driver mutations (overwhelmingly *JAK2V617F*). Ras pathway mutations are frequently found in CMML and aCML, although at lower frequencies, and their presence is correlated with an inferior prognosis. *JAK2* mutations are most commonly seen in MDS/MPN-RS-T, more rarely observed in MDS/MPN-U, and to a lesser extent, in CMML.

RISK STRATIFICATION AND PROGNOSIS

Chronic Myelomonocytic Leukemia Risk Stratification

Given the clinical heterogeneity of CMML, tailoring predicted patient outcomes to treatment options has been a fundamental cornerstone in developing treatment strategies. Multiple CMML-specific risk stratification models have been proposed and validated in recent years (Fig. 73.8).[11] Initial models were based on clinicopathologic features, and more recently, CMML-associated genetic mutations and their respective prognostic impact have led to the creation of the following three molecularly integrated models.

In 2013, the CMML-specific prognostic scoring system (CPSS) was conceived based on WHO- and FAB-defined CMML subtypes, CMML-specific cytogenetic abnormalities, and RBC transfusion dependence (Table 73.5). Three years later, the establishment of mutated *ASXL1* as a predictor of aggressive disease and inferior OS in CMML, as well as the concomitant adverse survival implications of *RUNX1*, *NRAS*, and *SETBP1* mutations led to the mutational status of these genes being incorporated into the CPSS-Mol risk stratification system. This score is calculated by first determining the CMML genetic score by assigning 1 point for intermediate risk cytogenetics and 2 points for high-risk cytogenetics, 1 point for an *ASXL1* mutation, 1 point for a *NRAS* mutation, 2 points for a *RUNX1* mutation, and 1 point for a *SETBP1* mutation. The genetic risk is then determined to be low (0 points), intermediate-1 (1 point), intermediate-2 (2 points) or high (3 or more points). The CPSS-Mol score is then calculated

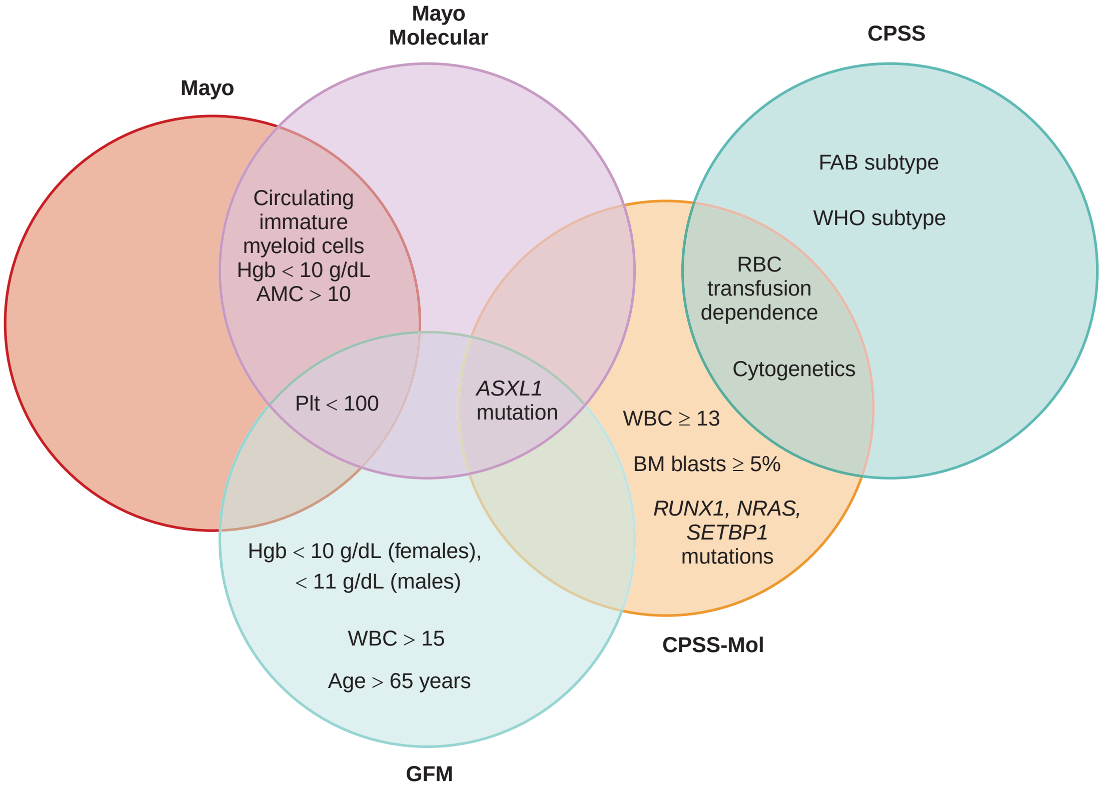

Figure 73.8 COMPARISON OF CHRONIC MYELOMONOCYTIC LEUKEMIA PROGNOSTIC STRATIFICATION SCORING SYSTEM. Five CMML prognostic stratification scoring systems are compared and contrasted via the individual risk factors recognized by each. *AMC*, Absolute monocyte count; *ASXL1*, additional sex combs like-1; *BM*, bone marrow; *CMML*, chronic myelomonocytic leukemia; *CPSS*, CMML-specific prognostic scoring system; *FAB*, French-American-British; *GFM*, Groupe Français des Myélodysplasies; *Hgb*, hemoglobin; *NRAS*, neuroblastoma RAS; *Plt*, platelets; *RBC*, red blood cell; *RUNX1*, Runt-related transcription factor 1; *SETBP1*, SET binding protein 1; *WBC*, white blood cells; *WHO*, World Health Organization. *(Adapted from Tremblay D, Rippel N, Feld J, et al. Contemporary risk stratification and treatment of chronic myelomonocytic leukemia. Oncologist. 2021;26[5]:406–421.)*

		ii. WBC count ≥13×10^9/L	1	NR	68	30	17
		iii. BM blast proportion ≥5%	1				
		iv. CPSS cytogenetic intermediate risk group*	1				
		v. CPSS cytogenetic high-risk group*	2				
		vi. *RUNX1* mutation	2				
		vii. *ASXL1* mutation	1				
		viii. *NRAS* mutation	1				
		ix. *SETBP1* mutation	1				

[a] WHO subtypes: CMML-1: blasts including promonocytes less than 5% in peripheral blood (PB), less than 10% in bone marrow (BM). CMML-2: blasts including promonocytes 5% to 19% in PB, 10% to 19% in BM, or when Auer rods are present irrespective of blast count.

[b] FAB subtypes—CMML-MD: WBC less than13 × 10^9/L, CMML-MP: WBC ≥13 × 10^9/L.

[c] CPSS cytogenetic risk groups: low risk (diploid karyotype or isolated -Y), intermediate risk (all abnormalities other than those of low-/high-risk groups), high risk (trisomy 8, abnormalities of chromosome 7, or complex karyotype).

[d] At least 1 RBC transfusion every 8 weeks over 4 months.

AMC, Absolute monocyte count; *ASXL1*, additional sex combs like-1; *(BM)*, bone marrow; *CPSS*, CMML-specific prognostic scoring system; *FAB*, French-American-British; *GFM*, Groupe Français des Myélodysplasies; *NRAS*, neuroblastoma RAS; *RBC*, red blood cell; *RUNX1*, Runt-related transcription factor 1; *SETBP1*, SET binding protein 1; *WBC*, white blood cells; *WHO*, World Health Organization.

by giving 1 point each for: BM blasts ≥5%, WBC ≥13 × 10^9/L, and RBC transfusion dependency and adding this to the genetic risk score (0 points for low, 1 point for intermediate-1, 2 points for intermediate-2, and 3 points for high risk). A total score of 0 indicates low risk, 1 indicates intermediate-1 risk, 2 to 3 indicates intermediate-2 risk, and ≥4 indicates high risk. The CPSS-Mol model provides significantly improved prognostic accuracy, subclassifying CMML patients into four distinct prognostic cohorts that are highly variable in terms of both survival and risk of evolution to AML (see Table 73.5).[12]

Similarly, the Mayo prognostic model was devised in 2013 based on studying clinical variables and outcomes of 226 CMML patients in which absolute monocyte count greater than 10 × 10^9/L, hemoglobin less than 10 g/dL, platelets ≤100 × 10^9/L, and the presence of circulating immature myeloid cells were found to have independent prognostic significance after multivariable analysis. Using these risk variables, patients were categorized as low risk (0 risk factors), intermediate risk (1 risk factor), or high risk (2 or more risk factors). This was followed by a 2014 two-center study ($n = 466$) that demonstrated the adverse impact of *ASXL1* mutations on survival outcomes and subsequently led to its integration into an updated Mayo molecular model (MMM) that identified four prognostically discrete risk groups. One point is assigned to each of the four features listed in the Mayo prognostic model, in addition to one point for an *ASXL1* frameshift or nonsense mutation. Low-risk group (0 points) have an estimated OS of 97 months, intermediate-1 risk group (1 point) have an estimated OS of 59 months, intermediate-2 risk group (2 points)

TABLE 73.6 Myelodysplastic Syndrome/Myeloproliferative Neoplasm Overlap Syndromes: Cytogenetic Abnormalities and Overall Outcomes

MDS/MPN Subtype	Overall Frequency Cytogenetic Abnormalities (%)	Most Common Cytogenetic Aberrations and Associated Frequency (%)	Median OS (Months)	Leukemic Transformation Rate
CMML	30%	• Trisomy 8 (23%) • -Y (20%) • Monosomy 7, del7q (14%) • 20q deletion (8%) • Trisomy 21 (8%) • Derivative 3q (8%)	20–40	15%–30%
aCML	30%–40%	• Trisomy 8 (17–27%) • Monosomy 7, del7q (6%) • Trisomy 9 (5%) • Trisomy 21 (5%) • Other: complex karyotype, del(12q)	14–30	40%
MDS/MPN-RS-T	20%	• Trisomy 8 (4%) • -Y (4%) • Other: complex karyotype	60–84	< 5%
MDS/MPN-U	50%	• Trisomy 8 (15%) • Monosomy 7/del(7q) (11%) • Del(20q) (7%) • Complex karyotype (15%)	19–26	16%
JMML	35%	• Monosomy 7 (26%)		Rare

aCML, Atypical chronic myeloid leukemia; *CMML*, chronic myelomonocytic leukemia; *JMML*, juvenile myelomonocytic leukemia; *MDS*, myelodysplastic syndrome; *MPN*, myeloproliferative neoplasm; *MPN-RS-T*, myeloproliferative neoplasm with ring sideroblasts and thrombocytosis; *MPN-U*, myeloproliferative neoplasm unclassifiable.

gave an estimated OS of 31 months, and high-risk patients (3 or more points) have an estimated OS of 16 months.

The third molecularly-integrated risk stratification tool was developed following a retrospective analysis of 312 patients with CMML conducted by the Groupe Français des Myélodysplasies (GFM) and includes five independent prognostic determinants; these include age greater than 65 years (2 points), hemoglobin less than 10 g/dL in females or less than 11 g/dL in males (2 points), platelets less than 100×10^9/L (2 points), WBC greater than 15×10^9/L (3 points), and *ASXL1* mutation status (2 points). The GFM model stratifies patients into three risk groups: low risk (0 to 4 points), intermediate risk (5 to 7 points), and high risk (8 to 12 points) with associated survivals not reached, 38.5 months and 14.4 months, respectively.

While no clear consensus has been established in terms of the optimal CMML prognostic model, mutational data have been repeatedly shown to be invaluable for the prognostication of CMML patients. Accordingly, the European Hematology Association and European LeukemiaNet panel have recommended the use of any of the above three molecularly integrated models for CMML risk stratification, or alternatively the CPSS or MD Anderson Prognostic Scoring System in the absence of mutational data.[12] Until a unified approach to CMML risk stratification is reached with further studies of large, mutationally and cytogenetically characterized CMML databases, the utilization of a molecularly-guided approach, when feasible, is recommended for refined CMML prognostication.

Chromosomal Abnormalities Associated With Myelodysplastic Syndrome/Myeloproliferative Neoplasm Overlap Syndromes

While the MDS/MPN overlap syndromes share many clinicopathologic and molecular features, they retain important cytogenetic heterogeneity that has prognostic implications. There are no specific cytogenetic abnormalities for this group of disorders. Most of the recurrent chromosomal aberrations are also detected in other myeloid disorders. Cytogenetic abnormalities are seen in variable numbers among MDS/MPN overlap syndrome patients, namely in approximately 30%, 30% to 40%, 20%, 50%, and 35% in CMML, aCML, MDS/MPN-RS-T, MDS/MPN-U, and JMML patients, respectively (Table 73.6).[13–15] The presence of genomic abnormalities in MDS/MPN overlap syndrome patients can be used for risk stratification. Overall, these aberrations have been associated with inferior survival outcomes in all overlap syndromes, except for aCML. In a study of 367 MDS/MPN overlap patients, an abnormal karyotype was documented in 29% of patients, while a complex karyotype (defined as ≥3 aberrations) was only observed in 4% of patients. An abnormal karyotype was associated with inferior OS in all subtypes except aCML. Importantly, in MDS/MPN-RS-T, cytogenetic abnormalities are rare, but when present confer a poor prognosis.[6]

In CMML, the most common cytogenetic abnormalities are trisomy 8 (23%), loss of chromosome Y (20%), monosomy 7/7q deletion (14%), trisomy 21 (8%), 20q deletion (8%), and derivative 3q (8%). Two three-tiered systems have guided CMML-specific cytogenetic risk stratification. The Spanish group classified patients into low risk (normal karyotype or -Y), intermediate risk (all chromosomal abnormalities except those in the high and low risk categories), and high risk (trisomy 8, chromosome 7 abnormalities, and complex karyotype) categories, with associated five-year OS rates of 35%, 26%, and 4%, respectively. The Mayo-French system then revised the previously proposed categories by adding derivative 3q to the low-risk group, and including all monosomal karyotypes in the high-risk group, with resultant median OS of 41, 21, and 3 months in the low, intermediate, and high-risk categories, respectively.

Atypical Chronic Myeloid Leukemia Prognosis

aCML is associated with an aggressive disease course, with a median OS of 14 to 30 months and an AML transformation rate of 40% within 11–18 months. Multivariable analyses have implicated several factors as independent adverse prognosticators in terms of overall or progression-free survival in aCML, namely advanced age, progressive anemia, leukocytosis (with suggested peripheral leukocyte count cut-off of >50 × 10^9/L), increased numbers of immature precursors in the peripheral blood, female gender, and presence of *SETBP1* and/or *TET2* mutations.[16]

Multiple studies have investigated the cytogenetics of aCML, with variable frequencies of abnormalities detected; among the most frequent being trisomy 8 (17% to 27%) and chromosome 7 abnormalities (6%).[6,14]

Myelodysplastic Syndrome/Myeloproliferative Neoplasm With Ring Sideroblasts and Thrombocytosis Prognosis

Of the MDS/MPN overlap syndromes, MDS/MPN-RS-T patients have the most favorable outcome, with a median OS of 5 to 7 years and a leukemic transformation rate of <5%. Cytogenetic abnormalities are infrequent in MDS/MPN-RS-T, with a normal karyotype being identified in 80% of patients, and the most frequent chromosomal abnormalities being trisomy 8 (4%) and -Y (4%). Nonetheless, when present, an abnormal karyotype, along with anemia (hemoglobin <10 g/dL), and/or the presence of *SETBP1* and *ASXL1* mutations, have been linked to an inferior survival. In contrast, age less than 80 years, as well as *JAK2* and *SF3B1* mutations, independently predict a more favorable survival.

Myelodysplastic Syndrome/Myeloproliferative Neoplasm Unclassifiable

Among the MDS/MPN overlap syndromes, MDS/MPN-U remains the least characterized. In total, 50% of MDS/MPN-U patients have cytogenetic abnormalities, most commonly trisomy 8 (15%), a complex karyotype (15%), and monosomy 7 (10%).[15] The median OS of MDS/MPN-U is 19 to 26 months, with a 16% leukemic transformation rate. Advanced age (>65 years), adverse cytogenetics (involving chromosome 7 or a complex karyotype, increased BM or peripheral blood blasts (≥5%), and *CBL* and/or *TP53* mutations have all been shown to independently portend an inferior OS.[15,16]

While specific prognostic tools are not present for MDS/MPN-U patients, two studies have suggested the use of the utility of the MDS international prognostic scoring system (MDS-IPSS) for risk stratification.[15,17] Using the MDS-IPSS in MDS/MPN-U patients is limited, however, as the majority of patients are classified as being low-risk. Despite this categorization, low-risk MDS/MPN-U patients have an inferior survival as compared to their similarly-categorized MDS counterparts. The median survivals of MDS/MPN-U categorized by the IPSS-R as very low, low, intermediate, and high risk are 33.4, 25.1, 12.8, and 6.0 months.

Juvenile Myelomonocytic Leukemia Prognosis

Without appropriate treatment, JMML patients have a median survival of 10 to 12 months, with spontaneous complete remissions being reported in rare cases. Even with alloSCT, which is the only curative option for most, 5-year event-free survival (EFS) remains dire at about 50%.

As previously described, in JMML, germline mutations in Ras pathway genes (*NRAS*, *KRAS*, *PTPN11*) are associated with Noonan syndrome and confer a good prognosis and, on occasion, have even been associated with spontaneous remissions. On the contrary, the secondary acquisition of somatic *RAS* mutations and mutations in *SETBP1* and *JAK3* have been implicated in both disease progression to AML and an inferior OS. Other factors associated with adverse prognosis in terms of EFS and OS include older age at presentation (>2 years), increased fetal hemoglobin levels, peripheral and/or BM greater than 20%, increased DNA methylation profile, and a complex cytogenetic pattern. Cytogenetic abnormalities are seen in about 35% of JMML patients, usually in *KRAS*-mutated JMML, with monosomy 7 being the most common (26%).

TREATMENT APPROACHES

General Treatment Considerations

Treatment of patients with MDS/MPN overlap syndromes can be challenging given their clinical heterogeneity and the rarity of these diseases, resulting in many clinicians being unfamiliar with proper management strategies. Therapies in MDS/MPN overlap syndromes are largely borrowed from MDS or MPN treatment paradigms. Few clinical trials have evaluated agents dedicated for treating patients with MDS/MPN overlap syndrome. Among MDS/MPNs, CMML is by far the most thoroughly evaluated; thus, similar treatment strategies have been applied to the other MDS/MPN overlap syndromes given the shared biologic and clinical features. In general, asymptomatic patients without significant cytopenias can often be managed with observation alone. Patients with proliferative symptoms (e.g., leukocytosis) are often treated with hydroxyurea (HU) and occasionally the JAK1/JAK2 inhibitor ruxolitinib, particularly if splenomegaly or constitutional symptoms compromise the patient's quality of life. For patients whose MDS/MPN overlap syndromes with dysplastic features, hypomethylating agents (HMAs) are often employed. AlloSCT is the only curative therapy for all patients with an MDS/MPN overlap syndrome.

GENERAL TREATMENT CONSIDERATIONS

Risk stratification is key for the proper management of MDS/MPN. There are numerous prognostic scoring systems available for CMML, with no clear advantage between the three systems that incorporate mutational information: MMM, CPSS-Mol, and GFM. In practice, we use the CPSS-Mol given its ability to discriminate between risk groups. This scoring system is the only one that incorporates both cytogenetic and molecular data. Other MDS/MPNs overlap syndromes do not have formal risk stratification scoring systems, but certain risk factors portend worse prognosis. Specifically, *SETBP1* and *ASXL1* mutation in MDS/MPN-RS-T, anemia and leukocytosis in aCML, and *CBL* and *TP53* mutations in MDS/MPN-U are associated with inferior survival.

Independent of MDS/MPN subtype, patients who are high risk and eligible should proceed with alloSCT. In high-risk patients, HMA therapy can be employed in patients with cytopenias or elevated blast counts either in preparation for alloSCT or in transplant-ineligible patients. Ruxolitinib may be utilized to treat constitutional symptoms and splenomegaly, particularly in patients with CMML and MDS/MPN-U that are driven by activation of the JAK-STAT signaling pathway. Management of anemia in MDS/MPNs can be challenging, although ESAs can be successfully employed when the serum EPO level is less than 500 IU/L. Lenalidomide may be an option for some patients, particularly those with MDS/MPN-RS-T. Cytoreduction with HU is generally reserved for asymptomatic CMML patients with leukocytosis or splenomegaly and for select MDS/MPN-RS-T patients where anemia is not severe. Intensive chemotherapy should only be employed for rapidly progressive disease with elevated blast counts in preparation for definitive alloSCT.

aCML, Atypical chronic myeloid leukemia; *CMML*, chronic myelomonocytic leukemia; *ESA*, erythropoietin stimulating agent; *EPO*, erythropoietin; GFM, Groupe Français des Myélodysplasies; *HMA*, hypomethylating agent; HU, hydroxyurea; *MDS*, myelodysplastic syndrome; *MMM*, Mayo molecular model; *MPN*, myeloproliferative neoplasm; *MPN-RS-T*, myeloproliferative neoplasm with ring sideroblasts and thrombocytosis; *MPN-U*, myeloproliferative neoplasm unclassifiable

Chronic Myelomonocytic Leukemia Management

The first treatment decision for a patient with CMML is to determine if they are candidates for alloSCT. While advanced age, comorbidities, and lack of available donors remain exclusion criteria for many patients, advances in utilizing reduced intensity conditioning regimens and alternative donor sources are broadening the application of alloSCT. Importantly, to date, there has not been a prospective evaluation of alloSCT in CMML patients. However, many well-conducted retrospective studies provide evidence that alloSCT plays a key role in the treatment of CMML. A European Society for Blood and Marrow Transplantation (EBMT) study of 513 CMML patients undergoing alloSCT estimated a 4-year relapse-free survival and OS of 27% and 33% and a non-relapse mortality of 41%. Grade 2 to 4 acute and chronic graft-versus-host disease (GVHD) occurred in 33% and 24% of patients, respectively. The only statistically significant prognostic factor after multivariable analysis was attaining a complete response (CR) as judged by clinical parameters prior to transplant.[18] AlloSCT was associated with a longer OS as compared with non-transplant approaches (4.3 years vs. 2.0 years) in one retrospective study. However, the benefit for alloSCT extended only to CPSS intermediate-2 or high-risk patients and not to patients with intermediate-1 or low-risk disease.

Risk stratification is the first step for determining the appropriate treatment course for a patient with CMML. As previously discussed, the molecularly enhanced models are preferred but a consensus as to the optimal risk stratification scoring system does not exist. We typically employ the CPSS-Mol score given its ability to categorize patients into four risk groups with disparate clinical outcomes including OS and risk of leukemia transformation; however, each of the molecularly-informed prognostic models is acceptable in clinical practice when mutational information is available. In low-risk asymptomatic patients without anemia, observation may be appropriate. Low-risk patients should be closely monitored for the development of new symptoms, splenomegaly, or changes in their peripheral blood counts. Recent evidence suggests that leukocytosis (WBC above 34.25×10^9/L) in MPN-CMML patients is associated with higher rates of end organ damage, including renal insufficiency, liver dysfunction, pleural effusions, and cardiovascular events. In this study, patients with a WBC above 34.25×10^9/L who were treated with HU had a superior median OS compared to those who were not (24.7 months vs. 12.3 months, $P = .003$). Therefore, consideration of cytoreduction with HU in asymptomatic patients with a WBC greater than 34.5 g/dL is appropriate, although the true benefit has not yet been confirmed in a prospective study.

In low-risk patients with anemia, erythropoietin stimulating agents (ESAs) are frequently used to alleviate symptomatic anemia. In a study of 94 CMML patients who were treated with an ESA, 64% had an erythroid response (defined as an increase in hemoglobin of 1.5 g/dL) and 31% achieved transfusion independence. Similar to MDS, lower erythropoietin (EPO) levels were significantly associated with a response. This study also confirmed that ESAs are best utilized in low-risk patients. Although this study viewed EPO levels as a continuous variable, a cutoff level was not found to be predictive of an optimal response, although prior work in low-risk MDS suggests that patients with an EPO level of $\geq$500 U/L are unlikely to respond to an ESA. Therefore, it is reasonable to consider an ESA in anemic CMML patients who have an EPO level less than 500 U/L.

Lenalidomide has been evaluated in two clinical trials in CMML. In a phase I trial, lenalidomide 5 mg daily administered continuously was identified as the maximally tolerated dose and resulted in one partial response (PR) by MDS response criteria. Combination therapy with lenalidomide and azacitidine has also been explored in the Southwest Oncology Group (SWOG) S1117 study. This phase II/III clinical trial randomized CMML or high-risk MDS patients to azacitidine alone or in combination with lenalidomide or the histone deacetylase inhibitor vorinostat in a 1:1:1 fashion. There was a signal for superior efficacy in the CMML population with azacitidine plus lenalidomide as compared to azacitidine alone (overall response rate [ORR] of 68% vs. 28%). The median duration of response was 19 months. Unfortunately, the type of response (e.g., erythroid hematologic improvement) was not reported. Skin rashes were more common with the combination therapy as compared with azacitidine alone. In clinical practice, lenalidomide is occasionally utilized in CMML patients who have transfusion-dependent anemia based on data extrapolated from MDS where lenalidomide can result in conversion to transfusion independence in approximately a quarter of non-del(5q) MDS patients.

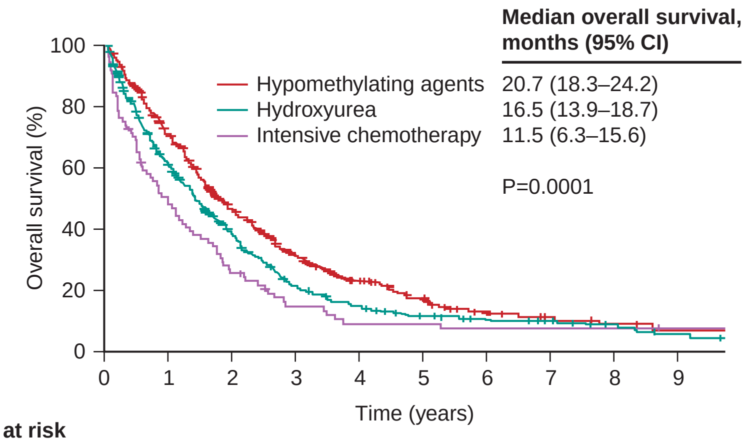
Another therapy that may improve erythropoiesis and ameliorate transfusion dependence in CMML patients is luspatercept, a novel fusion protein that contains an extracellular domain of the activin receptor II B fused to the Fc domain of human IgG1 and acts to trap activin and GDF11, which in turn inhibits Smad2/3 signaling thereby promoting differentiation of cells in the erythroid series. This agent is FDA approved for the treatment of MDS (see Chapter 61) and has been explored in CMML. In the phase I/II PACE-MD trial, which included patients with lower-risk MDS or MDS-CMML, the rate of erythroid improvement was 63% at 12 weeks. Responses were higher in patients who harbored an *SF3B1* mutation or had ring sideroblasts. However, patients with CMML were not included in the phase III MEDALIST trial that led to the approval of luspatercept in MDS patients with ring sideroblasts and MDS/MPN-RS-T. Further studies of CMML patients are needed to better understand the true role of luspatercept therapy.

Cytoreduction is the mainstay of therapy in MPN-CMML. While several cytoreductive agents have been explored, HU has been shown to produce superior response rates, longer OS, and improved tolerability as compared to more intensive therapies, as demonstrated in a trial of 105 CMML patients who were randomized to either HU or etoposide. The study closed after the first interim analysis, and the HU arm resulted in significantly longer survival compared to the etoposide arm (20 months vs. 9 months). In addition, HU treatment resulted in a higher response rate as compared with etoposide (60% vs. 36%).

There is only a limited role for intensive AML type induction chemotherapy in the treatment of CMML. In a retrospective analysis of MDS patients that also included patients with CMML, intensive induction therapy was associated with an inferior OS as compared to treatment with decitabine (12 months vs. 22 months). More recently, a large retrospective study of 949 CMML patients, including 83 who received intensive chemotherapy, demonstrated that intensive chemotherapy was associated with a survival of only 14 months as compared with 20.7 months in patients treated with an HMA (Fig. 73.9).[19] As such, most experts reserve intensive chemotherapy for fit patients who have rapidly increasing blast cell counts as a bridge to definitive therapy with alloSCT.

HMAs are the only FDA-approved agents for the treatment of CMML patients. The approval is based on prospective data of a limited number of CMML patients who were included in studies evaluating these agents in the MDS population. Specifically, the phase III registration studies of decitabine and azacitidine included only 14 patients each with CMML and presumably these patients had MDS-CMML. Despite this limited population of CMML patients, the efficacy of HMA has been subsequently confirmed in a prospective study of decitabine that included 43 CMML patients. In this study, the ORR was 47% and the CR rate was 16%. The median OS was 17 months, with responders having a significantly longer OS as compared with non-responders. Importantly, 9 out of 18 transfusion-dependent patients became transfusion independent.[20] Numerous retrospective studies of HMAs in CMML have confirmed their efficacy and safety, with most studies reporting an ORR of approximately 40% and CR rates of 10% to 20%.

The impact of HMA therapy, however, on OS and quality of life in CMML is less clear. In one matched-pair analysis, there was a trend toward increased two-year OS (62% vs. 41%, $P = .067$) in azacitidine-treated patients compared with best supportive case (BSC).[21] There is also no change in myeloid gene mutational burden following HMA therapy of CMML patients, as demonstrated by a study of mutation-specific discrimination analysis of treated CMML cases over



Number at risk (number censored)										
Hypomethylating agents	412 (0)	267 (26)	159 (44)	92 (61)	50 (81)	27 (91)	14 (98)	9 (102)	5 (104)	3 (105)

Intensive chemotherapy	83 (0)	38 (2)	20 (2)	10 (4)	6 (4)	6 (4)	5 (4)	5 (4)	5 (4)	4 (5)

Figure 73.9 Overall survival of 949 chronic myelomonocytic leukemia from treatment start comparing frontline intensive chemotherapy, hypomethylating agents, and hydroxyurea. Overall survival was significantly longer in patients treated with upfront hypomethylating agents. *(Adapted from Pleyer L, Leisch M, Kourakli A, et al. Outcomes of patients with chronic myelomonocytic leukaemia treated with non-curative therapies: a retrospective cohort study. Lancet Haematol. 2021;8[2]:e135–e148.)*

time. The authors observed amplification of more mutated clones in patients following treatment with HMA. In addition, there was ongoing clonal evolution despite clinical responses seen in patients with CMML treated with HMAs. Thus, while there are clear benefits for HMA therapy, it does not appear to significantly deplete the CMML stem cell clone.

HMAs have been compared to HU both in retrospective studies and in a phase 3 clinical trial. In a previously mentioned multicenter retrospective study including 949 CMML patients, first-line HMA treatment was associated with an improved OS as compared with HU (20.7 months vs. 15.6 months, $P = .0002$) (see Fig. 73.8). However, this survival advantage was not seen in patients with CMML-0, MDS-CMML, or lower-risk patients as defined by the CPSS score, highlighting the importance of patient selection.[19] HU and HMA therapy have also been prospectively compared in MPN-CMML patients in the phase 3 DACOTA study. One-hundred and seventy patients with MPN-CMML and advanced features (meeting at least two criteria: BM blasts ≥5%, abnormal karyotype (except -Y), absolute neutrophil count $\geq 16 \times 10^9$/L, hemoglobin <10 g/dL, platelets $<100 \times 10^9$/L or splenomegaly >5 cm below costal margin) were randomized to either decitabine or HU. After an intention-to-treat analysis, the ORR was 56% and 30% at 3 months for the decitabine and HU arms, respectively, a difference that was statistically significant ($P = .0011$). The duration of response was longer in the decitabine arm but not to a statistically significant degree. While there was no significant difference in EFS, OS, or AML-free survival between the two arms, one-third of patients in the HU arm went on to receive an HMA and more patients in the HMA arm went to alloSCT as compared with the HU arm. This prospective evaluation offers a few important insights. First, this trial demonstrates that randomized clinical trials in CMML are feasible, paving the way for more rigorous therapeutic studies of patients with this rare disease. Second, both HU and HMA are active agents in MPN-CMML. However, there may be an advantage to using HMAs upfront given that one-third of patients in the HU arm eventually went on to receive an HMA and upfront decitabine was associated with higher response rates and more patients proceeding to alloSCT. Long-term follow-up of this trial is eagerly awaited to clarify the upfront treatment for MPN-CMML patients.

Administration of HMAs has recently become more convenient with the approval of oral decitabine/cedazuridine. This agent combines oral decitabine with the cytidine deaminase inhibitor cedazuridine, resulting in bioequivalent doses of decitabine as compared with parenteral decitabine. In a randomized phase II study, 63 patients with MDS and 17 with CMML were randomized patients 1:1 to either oral cedazuridine 100 mg/decitabine 35 mg for 5 days in cycle 1 followed by IV decitabine 20 mg/m^2 in cycle 2 or the reverse (intravenous followed by oral). The ORR was 60%, and the CR rate of 21%. Grade ≥3 or adverse events included 46% with neutropenia, 38% with thrombocytopenia, and 22% with anemia. A phase III trial with a nearly identical design was then performed using a fixed-dose capsule and enrolled 133 patients (117 with MDS and 16 with CMML). The primary endpoint of bioequivalence between oral decitabine/cedazuridine and IV decitabine was achieved.[22] Based on this bioequivalence data, oral decitabine/cedazuridine was approved by the FDA approved for the treatment of MDS and CMML. Of note, the results of these studies do not report the outcomes of the subgroup of CMML patients. Importantly, based on the trial design, oral decitabine/cedazuridine was not compared directly to parenteral decitabine in terms of clinical endpoints and safety, but the response rates, cytopenias, and survival data appear consistent with what is expected for HMA therapy in CMML patients. A phase III trial comparing oral versus intravenous decitabine appears unlikely.

Novel therapies are currently in development for the treatment of CMML. Among the most promising is the JAK1/JAK2 inhibitor, ruxolitinib. In a phase 1 study of 20 patients with CMML, ruxolitinib treatment led to improvement in splenomegaly in 5 of 9 patients and symptomatic improvement in 10 patients out of 11.[23] In an expansion phase 2 trial which included an additional 29 patients, the ORR (by MDS/MDS International Working Groups criteria) was 46% and the OS was significantly prolonged as compared with historical controls. Although not FDA approved for CMML, ruxolitinib can be effective in patients with MPN-CMML who have constitutional symptoms or splenomegaly. Other novel agents in development for CMML include the GM-CSF blocking antibody lenzilumab, the CD123-directed cytotoxin tagraxofusp, and the farnesyltransferase inhibitor tipifarnib. In addition, multiple agents currently in clinical development for MDS may have a role in the future treatment of CMML.

One potential therapy that has recently been evaluated is pevonedistat, a neural precursor cell-expressed, developmentally downregulated 8 (NEDD8) activating enzyme inhibitor that regulates the activity of the cullin-dependent E3 ligases as part of the ubiquitin-proteasome system which leads to the accumulation of certain substrates involved in cell-cycle progression, DNA damage, and stress responses, causing cell death of AML and MDS cells. A phase II randomized trial of azacitidine either alone or in combination with pevonedistat, enrolled 120 patients with higher-risk MDS ($n = 67$), low-blast count AML ($n = 36$), or CMML ($n = 17$) patients has been completed. A significant increase in median OS with azacitidine in combination with pevonedistat versus azacitidine alone (21.8 months vs. 19.0 months, $P = 0.33$) was not observed. Since the number of CMML patients studied was small, further evaluation of this agent or other agents targeting this pathway are merited.

Atypical Chronic Myeloid Leukemia Management

As a rare and heterogeneous disease, there is a paucity of clinical trial data for treating aCML and an established standard of care is not available. Similar to other MDS/MPNs, HMAs, HU, and ESAs have been employed with varied success. The only curative therapy is alloSCT. The largest study of alloSCT in aCML was performed by the EBMT, which retrospectively analyzed the outcomes of 42 patients with aCML who received an alloSCT (64% with matched sibling and 36% with unrelated donor grafts). After a median follow up of 89 months, 87% of patients had achieved a CR with a median OS of 70 months. Acute and chronic GVHD was the major contributor to treatment-related mortality.[24] Therefore, for appropriate aCML patients, alloSCT should be pursued.

HMA therapy can be employed in alloSCT-ineligible patients or to control disease as a bridge to transplant in select patients. Data are largely borrowed from other MDS/MPNs, although several case reports and/or series describe the use of HMAs, largely decitabine, for the treatment of aCML. In the largest series of 19 aCML patients who received an HMA, the ORR was 26%. However, the median duration of response was only 2.7 months. The impact of HMA therapy on cytogenetic and mutational burdens in aCML patients has not been documented. At present, HMAs are likely best utilized as a cytoreductive bridge to alloSCT, although they are frequently administered in transplant-ineligible patients with unclear efficacy.

Additional therapies are being actively evaluated. With the discovery of the *CSF3R T618I* membrane proximal mutation that results in downstream JAK-STAT pathway activation, there is laboratory-based rationale for the utilization of ruxolitinib. There are numerous case reports demonstrating the activity of ruxolitinib in patients with aCML, including a phase II trial of single agent ruxolitinib. In this study, which included 44 patients with aCML or CNL, the ORR was 35%. However, only 2 of the 23 patients with aCML responded (both were a PR). The duration of response was not reported, but the median time of ruxolitinib administration was only 5.5 months in the aCML group (compared to 15.3 months in the CNL arm). Responses were more likely in patients harboring a *CSF3R* mutation and survival between the CNL cohort and aCML were not statistically different. Ruxolitinib therapy led to a greater reduction of median WBC/absolute neutrophil count in patients with CNL (vs. patients with aCML) and in *CSF3R*-mutated patients (vs. *CSF3R*–wild type patients). Spleen volume reduction ≥ 35% occurred more frequently in *CSF3R*-mutant patients (79% vs. 29% in *CSF3R*-wild type patients; but this did reach statistical significance). The majority of patients did not experience CR or PR and eventually succumbed to disease-related complications unless they proceeded to alloSCT.[25] Therefore, ruxolitinib should only be considered for the treatment of aCML in the presence of the *CSF3R T618I* mutation, but this therapy is associated with treatment-emergent myelosuppression and an unclear survival benefit. Given the complexity of aCML, referral to a center with expertise in this area is essential for the management of aCML.

Myelodysplastic Syndrome/Myeloproliferative Neoplasm With Ring Sideroblasts and Thrombocytosis Management

The management of MDS/MPN-RS-T patients is primarily aimed at symptom management, with an emphasis on risk stratification. Treatment strategies are borrowed from both essential thrombocythemia (ET) (see Chapter 71) and MDS-RS (see Chapter 61). However, given the rarity of MDS/MPN-RS-T, the true efficacy and safety of these treatment strategies have not been completely explored.

In patients with low-risk MDS/MPN-RS-T, aspirin may be employed (although it has not been formally evaluated in MDS/MPN-RS-T) to reduce vasomotor symptoms, such as migraine headaches and erythromelalgia. Aspirin may also reduce the thrombotic risk; however, the true benefit of this strategy is debated even in low-risk ET patients (see Chapter 71). Of note, there is no established relationship between the height of the platelet count and the degree of thrombotic risk in ET. Therefore, it is assumed that such a correlation does not exist in MDS/MPN-RS-T. Thus, cytoreductive agents should not be employed to lower the platelet count in the absence of vasomotor symptoms or thrombotic events, especially as these agents will likely exacerbate the underlying anemia. Instead, reduction in symptom burden should be the goal of cytoreductive therapy. In addition, in patients who have severe bleeding events secondary to acquired von Willebrand syndrome due to excessive thrombocytosis, cytoreductive therapy with HU is appropriate. Another option is anagrelide, which selectively reduces platelets but is associated frequently with cardiac and gastrointestinal toxicity and anemia (see Chapter 71). Pegylated interferon-2α can also be used in select patients who are intolerant to HU but will likely lead to greater degrees of anemia. However, none of these therapeutic agents has been thoroughly evaluated specifically in MDS/MPN-RS-T. Ruxolitinib may have a role in appropriate patients with constitutional symptoms who can tolerate treatment-related anemia associated with this agent.

Amelioration of anemia is a key challenge in MDS/MPN-RS-T. Similar to MDS and CMML, ESAs are most appropriately employed in low-risk patients. Given the experience in MDS and CMML with ESAs, patients with lower EPO levels (i.e., <500 mU/mL) are most likely to respond. Lenalidomide has also been explored in MDS/MPN-RS-T patients. Case reports have consistently demonstrated erythroid responses and platelet reductions with occasional molecular responses. However, changes in BM morphology have not been noted. Luspatercept is also likely to have a role in improving anemia in MDS/MPN-RS-T patients, given its efficacy in patients with MDS-RS and in patients that harbor the *SF3B1* mutation. However, luspatercept has not been systematically evaluated in MDS/MPN-RS-T patients. However, in patients with anemia who do not respond to ESAs and/or lenalidomide, luspatercept is a reasonable option. As with other MDS/MPNs, alloSCT should be strongly considered in appropriate high-risk patients.

Myelodysplastic Syndrome/Myeloproliferative Neoplasm Unclassifiable Management

Similar to other MDS/MPNs, there are no dedicated guidelines for the treatment of MDS/MPN-U. Given that this diagnosis is associated with a poor prognosis, with a median OS of approximately 12 to 24 months, appropriate patients should be rapidly referred for alloSCT. In terms of treatment options, HMAs are most commonly employed but their efficacy is not well established. In a series of 135 patients with MDS/MPN-U, 59 patients (44%) were treated with an HMA. In the 27 patients who completed at least 6 cycles of HMA treatment and, therefore were evaluable for response, only 1 patient (4%) attained a CR while 2 patients (7%) attained a partial PR. In addition, 3 patients (11%) had a marrow response and 1 patient (4%) had a complete cytogenetic response, leading to an ORR of 19%. Of note, the duration of response in this series was not reported. Notably, 1 patient with a CR and 1 with a PR eventually transformed to AML while receiving treatment. Therefore, while HMA responses are possible in MDS/MPN-U, the response rate is suboptimal.

As with the other MDS/MPN overlap syndromes, alloSCT is the only curative option. In a Japanese study utilizing a nationwide registry, 86 patients were identified who received an alloSCT. The 3-year OS was 48.5%, with cumulative incidence of relapse of 23.7% and non-relapsed mortality of 26.3%. Age older than 50 years and active disease at time of alloSCT were predictive of an inferior survival.

In terms of novel therapies for MDS/MPN-U, ruxolitinib in combination with azacitidine has been prospectively explored in a phase 2 study of MDS/MPN overlap syndrome patients (CMML, aCML, MDS/MPN-U) that included 14 patients with MDS/MPN-U. The median duration of treatment was 13.8 months. Of the entire cohort of 35 patients, 57% had a response. In the 14 patients with splenomegaly at baseline, 9 (64%) had a spleen response. The median duration of response was 8 months. The median OS of the entire study population was 16.6 months, but the median OS was longest in patients with MDS/MPN-U (26.5 months), as compared with CMML (15.1 months) or aCML (8 months). Therefore, ruxolitinib in combination with an HMA may be employed in MDS/MPN-U patients, particularly if splenomegaly and constitutional symptoms are present.

Juvenile Myelomonocytic Leukemia Management

The majority of children with JMML will require alloSCT. However, as previously discussed, patients with germline *PTPN11, NRAS,* or *KRAS* patients (Noonan syndrome) or those with germline *CBL* mutation may have spontaneous remission of their myeloproliferation and, therefore, a watch and wait approach is appropriate. In patients with somatic *PTPN11* or *KRAS* mutations or germline *NF1*, upfront alloSCT should be offered. In *NRAS* somatically mutated JMML patients who have favorable features, such as HbF levels ≤10% and normal platelet counts, observation may be appropriate.

It is sometimes necessary to provide therapy to bridge a JMML patient to alloSCT, particularly in the case of mild organ dysfunction or symptomatic splenomegaly. Azacitidine, oral 6-mercaptopurine, and low-dose cytarabine have been employed in this setting to leukoreduce patients. In children with blastic transformation or pulmonary infiltration causing respiratory compromise, fludarabine and high-dose cytarabine may be useful. However, there remains controversy whether pre-transplant JMML-directed therapy is appropriate for all patients. To date, standard chemotherapy regimens have not been shown to have an impact on the rate of post-alloSCT relapse. Of note, novel Ras-targeting therapies are in development but have not been clinically evaluated in patients with JMML.

If alloSCT is pursued, total body irradiation should be avoided given the inferior efficacy and late-onset adverse effects that have been reported. A busulfan-based myeloablative conditioning regimen is recommended. In terms of donor source, recent analyses suggest negligible differences between using grafts harvested from unrelated donors and HLA-identical siblings. In the largest study to date, the 5-year OS after alloSCT was 64% with 35% having recurrence of their leukemia. In patients who require timely transplantation or those who do not have a matched donor, umbilical cord blood transplantation (UBCT) has been shown to be efficacious with the 5-year disease free survival of 44%. Patients at an increased risk of death or relapse post-transplant include older children (≥2 years), those with platelet counts ≤40 × 10^9/L, and those with fetal hemoglobin levels ≥10%.

In children who experience post-alloSCT mixed donor/recipient chimerism or reappearance of cytogenetic or molecular alterations after alloSCT, there are several salvage treatment options. In children who are still on immunosuppression for GVHD prophylaxis, withdrawal of the immunosuppressive agents can lead to eradication of the malignant cells. In children off immunosuppressive therapy or with overt leukemic relapse, a second alloSCT should be pursued. Of note, donor lymphocyte infusion has been shown to be ineffective in this setting.

Clinical trials are ongoing looking at alternative therapies for JMML. Leveraging knowledge about the Ras/Erk pathway, the Children's Oncology Group is conducting a study evaluating trametinib (an oral MEK inhibitor) in relapsed or refractory JMML. Given the rare and severe nature of JMML, international and cooperative group studies are needed to identify additional therapies to improve survival and decrease toxicity associated with treatments for these young patients.

FUTURE DIRECTIONS

Since the designation of MDS/MPN overlap syndromes as a distinct diagnostic entity in 2002, advances in molecular and biologic characterization have generated translational science that will likely lead to the next generation of therapeutics. A key theme that has emerged is the genetic similarities between MDS/MPN overlap syndromes. Despite differing morphologic features, whole-exome and RNA sequencing studies have revealed that these overlap syndromes do not cluster and instead exist as a continuum with the majority of patients harboring ≥3 co-occurring mutations involving chromatin modifiers, epigenetic regulators, splicing factors, and signaling pathway genes.[26] Therefore, the future of therapeutic development in MDS/MPN overlap syndromes should involve the creation of shared treatment paradigms targeting key pathway mutations rather than the development of disease-specific therapies. With that in mind, the use of shared response criteria (Table 73.7) has enabled the evaluation of treatment options across the various MDS/MPNs overlap syndromes to facilitate future clinical investigation.[27] To further the development of novel therapeutic in MDS/MPNs, international collaboration will be necessary to combine expertise and optimize enrollment in these rare diseases.

Agents that are currently in development for other myeloid malignancies may also have a role in the treatment of patients with MPN/MDS overlap syndromes. For instance, the BCL-2 inhibitor venetoclax was recently reported to have activity in combination with an HMA for the treatment of CMML and AML secondary to CMML. In addition, targeting agents by mutational subtypes may hold promise in the future. At present, mutations in *IDH1* and *IDH2* are rare in patients with MDS/MPN overlap syndromes and can be targeted with approved small molecule inhibitors. In addition, novel agents in development that target spliceosome mutated myeloid malignancies, such as protein arginine methyltransferase inhibitors (i.e., PRMT5 inhibitor), may be particularly effective in MDS/MPNs given the high prevalence of splicing mutations.

CONCLUSION

MDS/MPN overlap syndromes are rare and heterogeneous entities featuring both proliferative features and BM failure. Morphologic differences in the subtypes are in contrast to recently defined shared pathogenetic features. Risk stratification to assess patient prognosis is key for the appropriate management of MDS/MPN, with alloSCT being the only curative option in fit, high-risk patients. Patients who experience symptomatic splenomegaly or constitutional symptoms may benefit from a JAK2 inhibitor therapy. HMA therapy can also be employed for the treatment of patients with MDS/MPNs overlap syndromes and can produce responses but such agents have an unclear impact on OS and the rate of disease progression. Novel therapies are in development, but multicenter, cooperative trials are needed to expand treatment options for MDS/MPN overlap syndromes, which have traditionally been associated with poor outcomes.

TABLE 73.7 Proposed Criteria for Measurement of Treatment Response in Adult Myelodysplastic Syndrome/Myeloproliferative Neoplasm Overlap Syndromes

CR (presence of all of the following improvements)[a]

- Bone marrow: $\leq$5% myeloblasts (including monocytic blast equivalent in case of CMML) with normal maturation of all cell lines and return to normal cellularity[a]
- Osteomyelofibrosis absent or equal to “mild reticulin fibrosis” ($\leq$ grade 1 fibrosis)[b]
- Peripheral blood[c]
  - WBC $\leq 10 \times 10^9$ cells/L
  - Hgb $\geq$11 g/dL
  - Platelets $\geq 100 \times 10^9$/L; $\leq 450 \times 10^9$/L
  - Neutrophils $\geq 1.0 \times 10^9$/L
  - Blasts 0%
  - Neutrophil precursors reduced to $\leq$2%
  - Monocytes $\leq 1 \times 10^9$/L
- Extramedullary disease: Complete resolution of extramedullary disease present before therapy (e.g., cutaneous disease, disease-related serous effusions), including palpable hepatosplenomegaly

Provisional category of CR with resolution of symptoms:[c] CR as described above, and complete resolution of disease-related symptoms as noted by the MPN-SAF TSS

Persistent low-level dysplasia is permitted given subjectivity of assignment of dysplasia[a]

Complete cytogenetic remission

- Resolution of previously present chromosomal abnormality (known to be associated with myelodysplastic, syndrome myeloproliferative neoplasms, or MDS/MPN), as seen on classic karyotyping with minimal of 20 metaphases or FISH[d]

Partial remission

- Normalization of peripheral counts and hepatosplenomegaly with bone marrow blasts (and blast equivalents) reduced by 50%, but remaining >5% of cellularity except in cases of MDS/MPN with $\leq$5% bone marrow blasts at baseline

Marrow response

- Optimal marrow response: Presence of all marrow criteria necessary for CR without normalization of peripheral blood indices as presented above.
- Partial marrow response: Bone marrow blasts (and blast equivalents) reduced by 50%, but remaining >5% of cellularity, *or* reduction in grading of reticulin fibrosis from baseline on at least 2 bone marrow evaluations spaced at least 2 months apart

Clinical benefit

- Requires 1 of the following in the absence of progression or CR/partial response and independent of marrow response (cord blood response must be verified at $\geq$8 weeks) to be considered a clinical benefit
- Erythroid response
  - Hgb increase by $\geq$2.0 g/dL
  - TI for $\geq$8 weeks for patients requiring at least 4 packed red blood cell transfusions in the previous 8 weeks
  - Only red blood cell transfusions given based on physician’s judgment for a pretreatment Hgb of $\leq$8.5 g/dL will count in the red blood cell TI response evaluatione[e]
- Platelet response
  - Transfusion independence when previously requiring platelet transfusions of at least a rate of 4 platelet transfusions in the previous 8 weeks
  - Pretreatment $\leq 20 \times 10^9$/L: increase from $< 20 \times 10^9$/L to $> 20 \times 10^9$/L and by at least 100%
  - Pretreatment $> 20 \times 10^9$/L but $\leq 100 \times 10^9$/L: absolute increase of $\geq 30 \times 10^9$/L[e]
- Neutrophil response
  - Pretreatment $\leq 0.5 \times 10^9$/L at least 100% increase and an absolute increase $\geq 0.5 \times 10^9$/L
  - Pretreatment, $> 0.5 \times 10^9$/L and $\leq 1.0 \times 10^9$/L At least 50% increase and an absolute increase $\geq 0.5 \times 10^9$/L[e]
- Spleen response
  - Either a minimum 50% reduction in palpable splenomegaly of a spleen that is at least 10 cm at baseline or a spleen that is palpable at more than 5 cm at baseline becomes not palpable
- Symptom response
  - Improvement in symptoms as noted by decrease of $\geq$50% as per the MPN-SAF TSS scoring <20 were not considered eligible for measuring clinical benefit.[f]

---

[a] Presence of dysplastic changes, which may be interpreted within the scope of normal range of dysplastic changes, may still exist in the presence of CR as allowed in MDS International Working Group. Marrow should exhibit age-adjusted normocellularity in CR.

[b] If there is no significant fibrosis present on the initial bone marrow biopsy, a second biopsy is not required to prove resolution of fibrosis. Grading of fibrosis in measurement of treatment response should be according to the European Consensus System.

[c] Given the current lack of a validated tool to assess complete resolution of symptoms in MDS/MPN, “CR with resolution of symptoms” (a complete resolution of disease-related symptoms as noted by the MPN-SAF TSS in presence of CR) will be a provisional category of disease response.

[d] Loss of cytogenetic burden of disease by (via FISH or classic karyotyping) known to adversely affect prognosis is required to reach complete cytogenetic remission. Decrease in the cytogenetic burden of disease must be by $\geq$50% (via FISH or classic karyotyping) to be indicative of a partial cytogenetic response. Given variability of fluorescent probes used in FISH, cytogenetic normalization via FISH will depend on the performance characteristics of the specific probes used.

[e] Resolution of abnormal peripheral blood counts must persist for at least 2 separate analyses over at least 8 weeks. In the case of proliferative MDS/MPN, CR will include resolution of thrombocytosis to a normal platelet count ($150–450 \times 10^9$/L) and resolution of leukocytosis to WBC $\leq 10 \times 10^9$ cells/L but $\geq 1.5 \times 10^9$/L. Hgb should be maintained greater than 11 g/dL and platelets $\geq 100 \times 10^9$/L without the support of transfusions. Clinical benefit may occur when these changes occur in absence of other changes required for CR or marrow response. Platelet and packed red blood cell TI would be considered for clinical benefit, and duration of TI should be monitored. Reduction in myeloid precursors (promyelocytes, myelocytes, metamyelocytes, nucleated red blood cells) to less than appreciable levels ($\leq$2% to 3%) and/or 1×10^9/L monocytosis in the absence of infection, cytokine treatment, or other reactive causes.

[f] MPN-SAF TSS validation among patients with MDS/MPN is currently under way (R.A. Mesa, personal communication, 2014).

CHAPTER 74

EOSINOPHILIA, EOSINOPHILIC NEOPLASMS, AND THE HYPEREOSINOPHILIC SYNDROMES

Peter Valent, Andreas Reiter, and Jason Gotlib

Eosinophils are highly specialized granulocytic effector cells that produce and store numerous biologically active mediators, including cytotoxic proteins, lipid mediators, chemotactic peptides, and cytokines (Table 74.1). Under various pathologic conditions, blood eosinophils transmigrate through the endothelial layer and invade various target organs, where these cells secrete their products into the surrounding tissues, thereby triggering inflammation, toxic damage, and tissue remodeling.[1] Since their initial characterization by Paul Ehrlich in 1879, eosinophils have been implicated in a number of systemic diseases and conditions characterized by blood and/or tissue eosinophilia (Table 74.2). During the past few decades, researchers have also gained a better understanding of the unique features and functions of activated eosinophils and of the specific roles some of their granule proteins and inducible lipid mediators may play in the pathogenesis of allergic, parasitic, neoplastic, and other diseases.[1] In addition, recognition of the eosinophil as a major pro-inflammatory and tissue-remodeling effector cell has fueled a surge of interest in this granulocyte.

Studies of the biochemistry, biologic activities, and tissue localization of distinct enzymatic and non-enzymatic cationic proteins derived from eosinophils have provided convincing evidence for their role in the pathogenesis of inflammation and tissue damage in eosinophil-associated diseases. The five cationic granule proteins that may play a role in eosinophil-related pathologies include two major basic proteins (MBP-1 and MBP-2), eosinophil peroxidase (EPX), and two ribonucleases, namely eosinophil cationic protein (ECP) and eosinophil-derived neurotoxin (EDN; see Table 74.1). Eosinophils also have the capacity to express toxic oxidative intermediates and other mediators of inflammation, as well as molecules that may contribute to the development of thrombosis and fibrosis. In addition, eosinophils are a rich source of DNA traps that may facilitate fibrin deposition, as well as the killing of microbial invaders.[2] A clinically important aspect is that the various mediators produced and released by (activated) eosinophils often act together to trigger thrombosis and tissue damage, especially when eosinophil expansion and activation is chronic and "treatment-resistant."

The process of determining the cause of eosinophilia is often frustrating for both the physician and the patient, and, in many instances, the resulting diagnosis is "eosinophilia of unknown etiology." Depending on laboratory standards and local guidelines, eosinophilia is defined as more than 0.4 to 0.5×10^9/L blood, detected by microscopy.

Diurnal variations in eosinophil counts are well documented, with minimum numbers appearing early in the morning and greatest numbers appearing late at night, mirroring circadian rhythms in adrenal corticosteroids. Although these variations are usually limited to a certain extent, basal eosinophil counts should be routinely measured during the daytime. Transient mild eosinophilia is commonly seen in allergic reactions, during and shortly after a bacterial infection, and in many other reactive states. Sometimes, transient eosinophilia may be substantial or even excessive. Such transient (<4 weeks) forms of reactive eosinophilia are considered harmless in most instances but should prompt the physician to search for certain underlying diseases, such as an occult allergy or an unrecognized infection.

Eosinophil disorders and related syndromes are a heterogeneous group of diseases characterized by marked expansion and persistent accumulation of eosinophils in the peripheral blood (PB) and other organ systems. In general, eosinophil disorders can be divided into (A) neoplastic states where eosinophils are monoclonal and (B) reactive states where eosinophil expansion is considered to be "poly-clonal" and triggered by eosinotropic cytokines, such as interleukin-5 (IL-5).[3] In both instances, hypereosinophilia (HE), defined by a persistent eosinophil count of $\geq 1.5 \times 10^9$/L blood, is typically present. Depending on the underlying disease and other factors, the HE state may or may not be accompanied by specific (HE-mediated) organ damage, also referred to as *hypereosinophilic syndrome* (HES). In many instances, HES-related organ damage manifests as overt thromboembolism (thrombosis) or fibrosis.[3] In other patients, organ damage is associated with less-specific findings, and may involve the skin, gastrointestinal (GI) tract, or the central nervous system (CNS). Based on the underlying condition, both HE and HES can be divided into familial, primary (neoplastic), and secondary (reactive) forms (Table 74.3).[3] Apart from these classical forms of HES, more specific syndromes associated with HE and HE-related organopathies have been described. Some of these syndromes are associated with a hereditary (germ-line) defect, whereas others are accompanied by distinct immunological abnormalities (Table 74.4A). Finally, HE may develop in the context of organ-restricted inflammatory conditions such as eosinophilic pneumonia or eosinophilic colitis (Table 74.4B).

A thorough examination of all clinical and laboratory parameters, including radiologic and imaging studies, bone marrow (BM) investigations, karyotype, and molecular studies, are required in order to establish the correct diagnosis (underlying disease and organ damage) in patients with initially unexplained HE.[3] This chapter provides an overview on the epidemiology, pathogenesis, course, prognosis, and clinical features of various eosinophil disorders. We also discuss developments in the field and the impact of molecular markers and targets. In addition, this chapter provides diagnostic algorithms and recommendations for the management and treatment of patients with eosinophil disorders.

EPIDEMIOLOGY

Little is known about the prevalence and incidence of primary eosinophil disorders (eosinophilic neoplasms) and HE-related syndromes, including HES. Based on the available literature, most eosinophil neoplasms and all types of HES are rare, and the same holds true for other HE-related conditions, such as the Gleich syndrome or Churg-Strauss syndrome (CSS), also known as eosinophilic granulomatosis with polyangiitis (EGPA). In an attempt to estimate the incidence of HES, data collected by the Surveillance, Epidemiology and End Results (SEER) database, sponsored by the National Cancer Institute, have been reviewed. A crude incidence of 0.035 cases per 100,000 person-years was found, and the male-to-female ratio was reported to be 1.47 to 1. The average age at diagnosis was 52.5 years, and the peak incidence was recorded in individuals aged 65 to 74 years.

TABLE 74.1 Eosinophil-Derived Molecules and Their Potential Role in Health and Disease

Eosinophil Product/ Molecule	Relevant Function(s)
Eosinophil-Related Enzymes	
Nonspecific esterase	Cytotoxic effects (microbes and tissue cells)
Catalase	Cytotoxic effects (microbes and tissue cells)
Acid phosphatase	Cytotoxic effects (microbes and tissue cells)
Lysophospholipase	Tissue inflammation
Phospholipase D	Migration, adhesion, vesicle transport, secretion
Hexosaminidase	Tissue inflammation and tissue remodeling
Arylsulphatase B	Lysosomal hydrolase
5-Lipoxygenase	Leukotriene production, angiogenesis
Leukotriene C4 synthase	Leukotriene production
Cyclooxygenase	Prostaglandin production
Histaminase	Histamine degradation
Eosinophil Basic Proteins	
Eosinophil peroxidase (EPX)	Cytotoxic effects (parasites, microbes, tissue cells)
Major basic protein-1 (MBP-1)	Cytotoxic effects (parasites, microbes, tissue cells)
Major basic protein-2 (MBP-2)	Cytotoxic effects (parasites, microbes, tissue cells)
Eosinophil cationic protein (ECP)	Cytotoxic effects, mucus secretion, fibrosis
Eosinophil-derived neurotoxin (EDN)	Cytotoxic effects (antiviral, RNase activity)
Chemokines	
Interleukin-8 (IL-8)	Leukocyte recruitment and activation
MIP-1-alpha (CCL3)	Leukocyte recruitment and activation
RANTES (CCL5)	Leukocyte recruitment and activation
Eotaxin (CCL11)	Further eosinophil recruitment
Growth Factors/Cytokines	
Interleukin-1-α (IL-1α)	Endothelial activation, inflammation
Interleukin-2 (IL-2)	Activation of T lymphocytes
Interleukin-3 (IL-3)	Amplification of eosinophil accumulation/ activation and basophil activation
Interleukin-4 (IL-4)	B-cell maturation and mast cell differentiation
Interleukin-5 (IL-5)	Amplification of eosinophil accumulation/ activation
Interleukin-6 (IL-6)	Lymphocyte maturation
Interleukin-13 (IL-13)	Bronchial hyperreactivity, mucus production, B-cell maturation
GM-CSF	Leukocyte/eosinophil accumulation/activation
TGF-α	Fibrosis, growth inhibition
TGF-β	Fibrosis, growth inhibition
TNF-α	Endothelial activation, inflammation, cachexia
Oncostatin-M (OSM)	Fibrosis, angiogenesis, paracrine mobilization of eosinophils via upregulated SDF-1 production in fibroblasts
Lipid Membrane-Derived Substances	
PAF	Bronchoconstriction, edema formation
TXB2	Platelet aggregation
LTC4	Mucus secretion
15-HETE	Diverse effects on blood and tissue cells
PGE1 and PGE2	Diverse effects on platelets, endothelial cells, fibroblasts and other tissue cells
Antifibrinolytic Mediators	
PAI-2	Antifibrinolytic and prothrombotic
Extracellular DNA traps	Fibrin deposition, antibacterial effect

CCL, Chemokine (C-C motif) ligand; *GM-CSF*, granulocyte–macrophage colony-stimulating factor; *LTC4*, leukotriene C4; *MIP-1-alpha*, macrophage inflammatory protein-1-alpha; *PAF*, platelet-activating factor; *PAI-2*, plasminogen activator inhibitor-2; *RANTES*, regulated on activation, normal T-cell expressed and secreted; *SDF*, stromal cell-derived factor; *TGF*, transforming growth factor; *TNF*, tumor necrosis factor; *TXB2*, thromboxane B2.

Childhood cases of HES have been reported but are very rare. Unfortunately, all these data have serious limitations and emphasize the need for more comprehensive epidemiologic studies using currently available diagnostic criteria and robust registries. A complicating issue is that HES may coexist with an underlying primary eosinophil disorder, a lymphoma, but also an allergy or another reactive condition.[3] In eosinophil neoplasms presenting with the *FIP1L1::PDGFRA* fusion gene (*F/P*), a clear male predominance is found. As a consequence, any HES registry, including patients with *F/P*+ eosinophilic leukemia and/or other *F/P*+ myeloproliferative neoplasms (MPNs) with eosinophilia (MPN-eo), will report an overall male predominance of HES, even if other HES types are evenly distributed between males and females. Indeed, no clear gender predominance has been reported in other groups of HE or HES. Familial forms of HE and HES have been described but are very rare. In these cases, a hyper-immunoglobulin (Ig)E syndrome or Omenn syndrome (OS) have to be excluded. No cases of familial *F/P*+ leukemia have been reported to date.

MORPHOLOGY AND PHENOTYPE OF EOSINOPHILS

Eosinophils contain three populations of granules, namely (1) electron-dense, round, primary progranules present mainly at the promyelocyte and myelocyte stages, (2) specific (secondary) eosinophilic granules with an electron-dense crystalloid core, specifically found in mature eosinophils, and (3) small-sized granules, which may contain catalase, acid phosphatase, and arylsulfatase.[1] The large, specific granule is the major source of cytotoxic and pro-inflammatory cationic proteins. Eosinophils also contain lipid bodies that may serve as a source of eosinophil eicosanoide-forming enzymes, including 5-lipoxygenase, leukotriene C4 (LTC4) synthase, and cyclooxygenase (see Table 74.1).

The immunological phenotype of human eosinophils is well established and may assist in eosinophil detection and enumeration by flow cytometry. In common with all leukocytes, eosinophils express leukosialin (CD43), the homing cell adhesion molecule HCAM (CD44), and the pan-leukocyte tyrosine phosphatase C (CD45).[4,5] In addition, eosinophils express several myeloid differentiation antigens, including LFA-1 (CD11a/CD18) and Siglec-3 (CD33).[5] These cell-surface antigens are also expressed on other myeloid cells, including monocytes and basophils. However, a few cell-surface structures are largely restricted to eosinophils and thus serve as cell-specific markers through which eosinophils can be detected and isolated. One of these markers is Siglec-8, an inhibitory receptor that, when crosslinked, mediates eosinophil apoptosis.[6] Apart from eosinophils, basophils also display Siglec-8 (Fig. 74.1).

TABLE 74.2 Conditions Associated With Eosinophilia

Reactive Conditions
Helminth infections (filariasis, toxocariasis, schistosomiasis, trichinosis, onchocerciasis, fascioliasis, strongyloidiasis, ascariasis, hookworm, echinococcus/hydatid disease)
Fungal infections (aspergillosis, coccidioidomycosis, cryptococcosis)
Scabies and other infestations
Bacterial infections (convalescent phase of pneumococcal pneumonia, chlamydial pneumonia, scarlet fever, other bacterial infections)
Viral infections (HIV infection, chronic active hepatitis)
Allergic reactions (asthma, rhinitis, bronchitis, urticaria,
Atopic diseases (atopic asthma, atopic dermatitis)
Drug reactions (allergic, toxic)
Administration of IL-2, IL-3, or GM-CSF
Autoimmune diseases/connective tissue diseases/vasculitis (Sjögren syndrome, rheumatoid arthritis, lupus erythematodes, hypersensitivity vasculitis, bullous pemphigoid, others)
Acute and chronic graft-versus-host disease
Angioblastic lymphoid hyperplasia (Kimura disease)
Lymphocytic/lymphoid variant HES (HES$_L$)
Endocrinologic Conditions
Addison disease
Neoplastic Conditions Involving the Hematopoietic System
Myeloid neoplasms
Mast cell neoplasms
Lymphoid neoplasms
Paraneoplastic Conditions
Solid tumors/malignancy
Lymphoproliferative neoplasms (B- or T-cell lymphoma, Hodgkin disease)
Langerhans cell histiocytosis
Idiopathic Forms
Idiopathic eosinophilia[a]
HE of uncertain (undetermined) significance (HE$_{US}$)
Idiopathic hypereosinophilic syndrome (HES$_I$)
Hereditary HE with unknown etiology or a known genetic disorder

GM-CSF, Granulocyte–macrophage colony-stimulating factor; *HE*, hypereosinophilia; *HES*, hypereosinophilic syndrome; *HES$_I$*, idiopathic HES; *HES$_L$*, lymphoid variant HES; *HE$_{US}$*, hypereosinophilia of undetermined (unknown) clinical significance; *HIV*, human immunodeficiency virus; *IL-2*, interleukin-2; *IL-3*, interleukin-3.

[a] Idiopathic mild eosinophilia (500 to 1500 eosinophils/µL blood = less than HE) of unknown etiology.

TABLE 74.3 Classification of Hypereosinophilia and Hypereosinophilic Syndromes

HE Variant	Abbreviation	Associated HES Variant
Familial/hereditary HE	HE$_{FA}$	Familial HES = HES$_{FA}$
HE of undetermined/ Unknown significance	HE$_{US}$[a]	Idiopathic HES = HES$_I$[a]
Neoplastic/primary HE	HE$_N$	Neoplastic HES = HES$_N$
Reactive/secondary HE	HE$_R$	Reactive HES = HES$_R$
		Lymphocytic variant = HES$_L$[b]

HE, Hypereosinophilia; *HES*, hypereosinophilic syndrome; *HES$_{FA}$*, familial HES; *HES$_I$*, idiopathic HES; *HES$_L$*, lymphocytic variant HES; *HES$_N$*, primary (neoplastic) HES; *HES$_R$*, reactive HES; *HE$_{US}$*, hypereosinophilia of undetermined (unknown) clinical significance.

[a] In patients with HE$_{US}$, the presence of HES is excluded by definition; as soon as HES is diagnosed in a patient with HE$_{US}$, the diagnosis changes to HES$_I$, unless an underlying etiology (condition/disease) is also found.

[b] HES$_L$ is regarded a special variant of HES$_R$.

TABLE 74.4A Rare Syndromes Accompanied by Hypereosinophilia

Syndrome	Characteristic Features and Laboratory Abnormalities
Gleich syndrome	Cyclic recurrent angioedema, fever, weight gain, elevated polyclonal IgM, increased interleukin-5 production, evidence of clonal T cells (CD3$^-$ T cells)[a]
Churg-Strauss syndrome (CSS) = eosinophilic granulomatosis with polyangiitis (EGPA)	Stage I: Asthma and rhinosinusitis (isolated)
	Stage II: Eosinophilic phase (HES-like)
	Stage III: Vasculitic phase defined by necrotizing (small-vessel) vasculitis and HE with pulmonary infiltrates and/or neuropathy (ANCA+ and ANCA– subvariants have been described)
Eosinophilia myalgia syndrome (EMS)	Severe myalgia ± fever (flu-like), edema, fatigue, weight loss, neurologic symptoms, skin abnormalities
	Epidemic cases have been reported to result from exposure to L-tryptophan (toxic oil syndrome).
Eosinophilic fasciitis (EF) = Shulman syndrome	Scleroderma-like condition with painful swelling of the skin and chronic induration (limbs and trunk) as well as laboratory signs of systemic inflammation
Omenn syndrome (OS)	Severe combined immunodeficiency (SCID) with well-populated lymphatic organs (OS paradox)
	Autosomal recessive genetic (pediatric) disease (recurrent mutations in *RAG1* or *RAG2*)
	Clinical findings: erythroderma, hepatosplenomegaly, lymphadenopathy, increased IgE, diarrhea, weight loss (GVHD-like condition with autoreactive T cells)
Hyper-IgE syndrome (HIES)	Hereditary immunodeficiency syndrome with elevated IgE, recurrent severe infections, often with skin eczema and facial anomalies
	Examples of mutations associated with HIES: Autosomal dominant variant: *STAT3* mutations Autosomal recessive variant: *DOCK8* mutations *PGM3* mutations

ANCA, Anti-neutrophil cytoplasmic antibodies; *DOCK8*, dedicator of cytokinesis 8; *GVHD*, graft-versus-host disease; *HE*, hypereosinophilia; *HES*, hypereosinophilic syndrome; *IgE*, immunoglobulin E; *PGM3*, phosphoglucomutase 3; *RAG*, recombination-activating gene; *STAT3*, signal transducer and activator of transcription-3.

[a] EGPA/CSS with clonal T cells is often regarded as special variant of lymphoid variant HES (HES$_L$).

Eosinophils express several cytokine receptors, such as the IL-5 receptor, granulocyte-macrophage colony-stimulating factor (GM-CSF) receptor, and IL-3 receptor. Moreover, eosinophils exhibit various chemokine receptors, including eotaxin receptors and CXC-chemokine receptor 4 (CXCR4), a receptor for stromal cell-derived factor (SDF)-1 (Table 74.5). Finally, eosinophils express diverse complement receptors (CRs), such as CR3 (CD11b/CD18) and C5aR (CD88), adhesion receptors, and Ig (Fc) receptors.[5] Several of these cell-surface markers have been considered as potential targets of therapy. However, aberrantly expressed or disease-specific markers for neoplastic eosinophils or reactive eosinophils have not been identified yet. Several studies have shown that eosinophils in HES patients may express increased amounts of CD11b, CD16, CD25, or/and HLA-DR compared to normal blood

TABLE 74.4B Organ-Restricted (Inflammatory) Conditions Accompanied by Eosinophilia

- Eosinophilic gastrointestinal disorders (EGIDs)
    - Eosinophilic esophagitis
    - Eosinophilic gastritis
    - Eosinophilic gastroenteritis
    - Eosinophilic colitis
- Eosinophilic pancreatitis
- Eosinophilic hepatitis
- Eosinophilic ascites
- Pulmonary eosinophilic syndromes
    - Eosinophilic asthma
    - Eosinophilic bronchitis
    - Eosinophilic pneumonia
    - Eosinophil pleuritis
- Eosinophilic nephritis
- Eosinophilic cystitis
- Eosinophilic endometritis and myometritis
- Eosinophilic mastitis
- Eosinophilic ocular disorders
- Eosinophilic myocarditis
- Eosinophilic synovitis
- Skin diseases/conditions associated with eosinophilia[a]
    - Allergic contact dermatitis
    - Atopic dermatitis
    - Drug reactions
    - Bullous pemphigoid and pemphigoid variants
    - Eosinophilic cellulitis (Wells syndrome)
    - Radiotherapy-related eruptions associated with eosinophilia
    - Eosinophilic pustular folliculitis
    - Infestations (parasitic) and infections (bacterial, viral, fungal) involving the skin
    - Mycosis fungoides
    - Pachydermatous eosinophilic dermatitis
- Kimura disease (skin and lymph nodes)
- Eosinophilic panniculitis

[a] Many other skin abnormalities can be accompanied by eosinophilia, especially when a systemic inflammatory disease process is present and triggers eosinophilia.

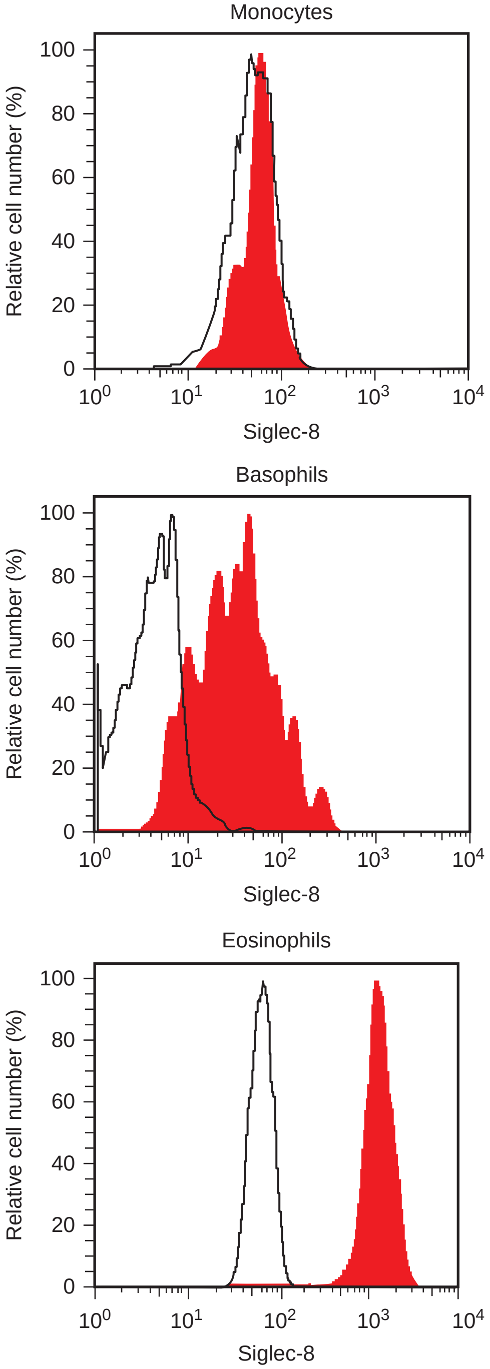

Figure 74.1 EXPRESSION OF SIGLEC-8 ON PERIPHERAL BLOOD EOSINOPHILS. Peripheral blood cells were obtained from a patient suffering from a myeloproliferative neoplasm with eosinophilia (MNP-eo). Cells were stained with an antibody against Siglec-8, as well as antibodies against CD203c (for basophil detection) and CD14 (for monocyte detection), and analyzed by multicolor flow cytometry. Siglec-8 is expressed on eosinophils (detected by their characteristic side-scatter properties and autofluorescence) as well as on blood basophils, whereas monocytes (like most other leukocytes) lack Siglec-8.

eosinophils. However, overexpression of these antigens on eosinophils is not disease-specific.

Apart from cell surface antigens, eosinophils also express more or less specific marker antigens in their cytoplasm by which these cells can be detected in various tissues by immunohistochemistry (IHC). Useful eosinophil IHC stains include ECP, EPX, and MBP-1 (Fig. 74.2A). Depending on the condition and underlying neoplasm, these antibodies may also react with (immature) basophils. Otherwise, however, the staining reaction appears to be largely specific for eosinophil granulocytes. Another important aspect is that some of the eosinophil proteins, like MBP, can be detected in tissue sections as deposit material after complete degranulation of eosinophils and even after their subsequent destruction (disappearance), which is often seen in the context of chronic HE-related tissue damage (HES).[7] Therefore, the definition of tissue HE includes not only the detection of a local eosinophil (cellular) infiltrate but also the presence of eosinophil protein deposits, even in the absence of infiltrating eosinophils.

Eosinophils from the PB and tissues of patients with HE may differ from their normal counterparts by morphologic, biochemical, and functional characteristics. The most important morphologic distinction is the one between immature and mature eosinophils. In most

TABLE 74.5 Receptors and Ligands Regulating Growth and Function of Eosinophils

Receptor (R) on Eosinophils	Ligand	Effects on Eosinophils
IL-2RA/CD25[a]	IL-2	Activation?[a] Migration?[a]
IL-3R/ CD123 + CD131	IL-3	Differentiation, survival, adhesion, migration, activation, priming
IL-4R/CD124	IL-4	Priming for effects of chemotaxins
IL-5R/ CD125 + CD131	IL-5	Differentiation, survival, adhesion, migration, activation, priming
GM-CSFR/ CD116 + CD131	GM-CSF	Differentiation, survival, adhesion, migration, activation, priming
IL-10R	IL-10	Inhibitory (activation, survival)
IL-12R	IL-12	Inhibitory (activation)
IL-13R	IL-13	Unknown
CD4	IL-16 (LCF)	Activation, priming
IL-25R	IL-25	Survival, activation
IL-27R	IL-27	Survival, activation
IL-33R/ST2	IL-33	Activation, survival
VEGFR-1/FLT-1	VEGF	Chemotaxis, activation
Tie-2/TEK	Angiopoietin-1	Chemotaxis, activation?
PDGFRA/B	PDGF	Activation and growth?
FGFR	FGF	Activation?
TGFβ1R	TGFβ1	Inhibitory (differentiation)
TGFβ2R	TGFβ2	Inhibitory (differentiation)
IFN-α-R	IFN-α	Inhibitory (growth)
IFN-γ-R	IFN-γ	Inhibitory (growth, migration)
CCR3 (CD193)	RANTES (CCL5)	Chemotaxis, activation
	MCP-3 (CCL7)	Chemotaxis, activation
	MCP-4 (CCL13)	Chemotaxis, activation
	Eotaxin-1 (CCL11)	Chemotaxis, activation
	Eotaxin-2 (CCL24)	Chemotaxis, activation
	Eotaxin-3 (CCL26)	Chemotaxis, activation
CXCR4 (CD184)	SDF-1 (CXCL12)	Chemotaxis
PAF-R	PAF	Chemotaxis, activation
C5aR (CD88)	C5a	Chemotaxis, activation
TLR1, 4, 7, 9, 10	Toll-like R-ligands	Survival, activation
Corticosteroid R	Corticosteroids	Inhibitory (activation)

CCL, Chemokine ligand; *CCR*, chemokine receptor; *CXCR4*, CXC-chemokine receptor 4; *FGF*, fibroblast growth factor; *GM-CSF*, granulocyte–macrophage colony-stimulating factor; *IFN*, interferon; *IL*, interleukin; *LCF*, lymphocyte chemoattractant factor; *MCP*, monocyte chemotactic protein; *PAF*, platelet-activating factor; *PDGF*, platelet-derived growth factor; *SDF*, stromal cell–derived factor; *TGF*, transforming growth factor; *VEGF*, vascular endothelial growth factor.

[a] Eosinophils derived from patients with hypereosinophilic syndromes (activated eosinophils) may express CD25. However, the role of CD25 in eosinophil function remains unknown.

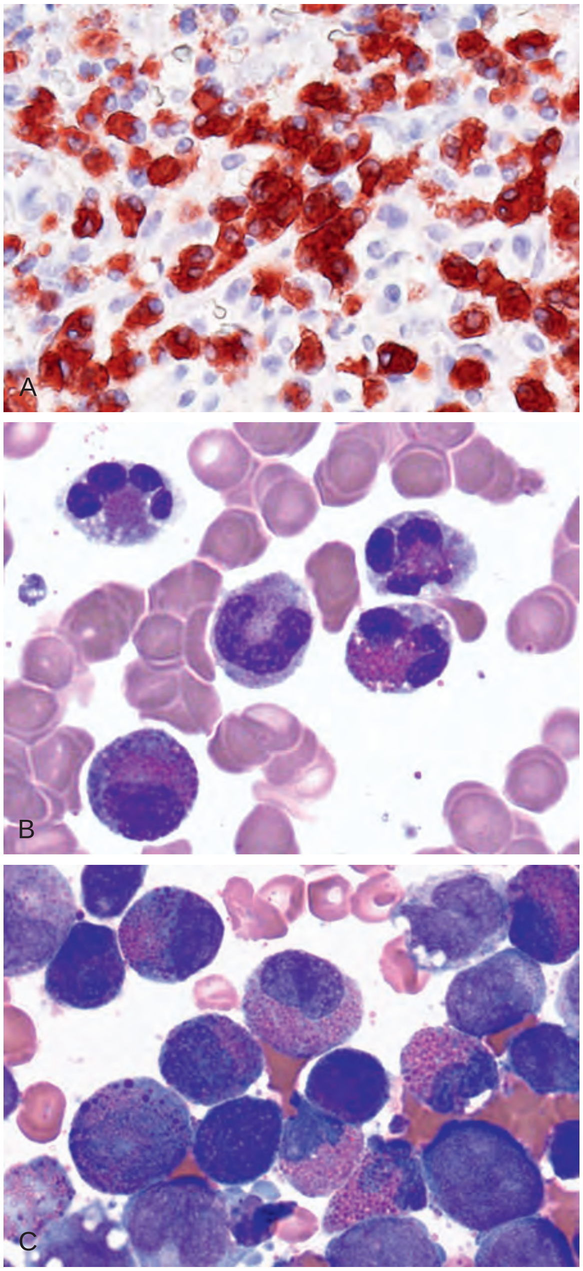

Figure 74.2 IMMUNOHISTOCHEMICAL AND MORPHOLOGIC PROPERTIES OF NEOPLASTIC EOSINOPHILS. (A) Expression of major basic protein (MBP) in neoplastic eosinophils in a patient suffering from a myeloid neoplasm with eosinophilia. Paraffin-embedded bone marrow sections were stained with an antibody against MBP by indirect immunohistochemistry. (B) Wright-Giemsa-stained bone marrow smear in a patient with chronic eosinophilic leukemia. Note the presence of atypical eosinophils, some of which contain multi-lobed nuclei. (C) Wright-Giemsa-stained bone marrow smear in a patient with an acute eosinophilic leukemia. The smear contains a mixture of immature and mature eosinophils. Some of the immature eosinophils exhibit a blast-like morphology. Other immature forms contain "basophilic" dark-blue granules, but these cells still belong to the eosinophil lineage.

instances, this distinction is a straightforward approach, as immature forms exhibit distinct nuclear and cytoplasmic morphologic features (Fig. 74.2B and C). However, sometimes the distinction may be challenging, especially in reactive states with massive inflammation and in certain myeloid neoplasms. In immature myeloid neoplasms, eosinophil precursor cells may exhibit dark basophilic granules that must not be confused with the specific granules of blood basophils. These immature eosinophils may also be misinterpreted as mixed-lineage (eosinophil/basophil) cells.

Immature eosinophils also differ from mature eosinophils in several other aspects, including density, nuclear shape, protein composition, and cell surface antigens. A difficult task is to differentiate normal eosinophils from activated (sometimes immature) eosinophils in reactive states. In previous years, researchers focused on cell density. In particular, a distinction was made between the "normodense" (normal-density) and the "hypodense" (light-density) eosinophil. The blood of normal individuals contains less than 10% eosinophils with densities less than 1.082 g/mL, whereas patients with eosinophilia can have markedly increased numbers of hypodense cells. Hypodense eosinophils often appear to be cytokine-activated cells that are characterized by increased vacuolization, decreased granule size, decreased content of granule cationic proteins, and increased numbers of cytoplasmic lipid bodies. The numbers of surface receptors for a variety of eosinophil agonists, including complement components, Igs, and platelet-activating factor (PAF), are expressed at higher levels by hypodense eosinophils. Functionally, hypodense eosinophils show increased metabolic activity and oxygen consumption, an increased capacity for the synthesis and secretion of LTC4 and certain cytokines, enhanced chemotaxis, and augmented cytotoxicity. So far, no clear relationship between the percentage of hypodense eosinophils and the etiology of eosinophilic disorders has been established. The percentage of these cells increases in most reactive forms of HE and HES, but also in patients with primary HES. Ultrastructurally, HES eosinophils may show a selective loss of secondary granule components (crystalloid MBP-containing core or granular matrix, or both), a decreased number and size of granules, and increased numbers of cytoplasmic lipid bodies and tubulovesicular structures that may be involved in eosinophil secretion during the process of piecemeal degranulation.

ORIGIN, DIFFERENTIATION, RECRUITMENT, AND ACTIVATION OF EOSINOPHILS

Eosinophilopoiesis

Eosinophils originate from pluripotent and granulocyte-committed, $CD34^+$, hematopoietic progenitor cells that are detectable in the BM and in the PB, and under certain conditions (local inflammation) also in various extramedullary organ sites. Eosinophil development from their multipotent and lineage-restricted progenitors is controlled by a network of transcription factors, including GATA-1, GATA-2, C/EBP-A, and C/EBP-E (see Chapter 9). Lineage-specific signaling as well as transcription factor expression is controlled by a network of cytokines and cytokine receptors. In fact, eosinophils develop from their progenitors in response to T-cell–derived growth factors, including IL-3, GM-CSF, and IL-5 (see Chapter 11). The most potent and specific eosinophilopoietic growth factor is IL-5.[1,8,9] Eosinophils are derived from multipotent or bipotent colony-forming progenitor cell units (CFUs). Bipotent CFUs giving rise to eosinophils and basophils (CFU-eo/ba) are frequently detected in the BM and PB in healthy individuals, as well as in various disease states.[8] By contrast, progenitor cells selectively giving rise to eosinophils and mast cells (CFU-eo/mast) are very rare. At an early stage of progenitor cell development, eosinophil-committed progenitors exhibit CD34 and CD38, and coexpress receptors for IL-3, GM-CSF, and IL-5. Later, CD34 expression is diminished, whereas the interleukin receptors continue to be expressed, and several additional, functionally important, cell-surface antigens are acquired by maturing eosinophils.

IL-3, GM-CSF, and IL-5 promote eosinophil differentiation of hematopoietic progenitor cells and eosinophil maturation of lineage-restricted precursors, as well as the recruitment, priming, activation, and survival of mature eosinophils.[9] Whereas IL-3 and GM-CSF also affect other hematopoietic lineages, including basophils, IL-5 acts as a more lineage-restricted (eosinophil-targeting) cytokine. Therefore, IL-5 and IL-5 receptors have been recognized as major targets of therapy in diseases associated with (reactive) HE. The high-affinity receptor for IL-5 is composed of an IL-5–specific alpha chain (CD125) and a beta chain (CD131) that mediates intracellular signaling and is shared also by the high-affinity receptors for GM-CSF (CD116/CD131) and IL-3 (CD123/CD131; see Table 74.5) (see Chapter 11). Expression of high-affinity IL-5 receptors is an important prerequisite for specific cellular responses to "physiologic doses" of IL-5. Overexpression of IL-5 is observed in many reactive conditions and disease states associated with (reactive) HE. Correspondingly, IL-5 transgenic mice develop profound eosinophilia, and IL-5 knockout mice do not develop HE in response to allergic stimuli or a helminth infection. Under various reactive conditions accompanied by HE, IL-5 is produced primarily by activated Th2-type helper cells. However, although activated T-cells are considered a primary and most important source of eosinophil-triggering cytokines, like IL-5, other cell types, such as mast cells, macrophages, natural killer (NK) cells, and stromal cells, also produce these cytokines. In myeloid neoplasms with HE, clonal expansion of eosinophils usually is a growth factor-independent process. Moreover, depending on the underlying disease, neoplastic eosinophils may produce eosinophilopoietic cytokines in an autocrine manner, thereby augmenting tissue and blood HE.

Mobilization and Migration of Eosinophils to Sites of Inflammation

In healthy individuals as well as in reactive states, eosinophils circulate only briefly in the PB, and then transit to extravascular sites.[9] Depending on environmental factors and demand, eosinophils localize preferentially in tissues and organs exposed to external environments, principally the submucosal membranes and loose connective tissues of the skin, GI tract, genital tract, and lungs. Depending on the underlying pathology, eosinophils can migrate into any vascularized organ. During an acute or chronic inflammatory process, larger numbers of eosinophils may be recruited actively into local tissue sites.[9] The mobilization of eosinophils from the vasculature into (vascularized) tissues is a multistep process that involves their rolling on vascular endothelial cells and their subsequent adhesion to endothelium via L-selectin, followed by binding to intercellular adhesion molecule-1 (ICAM-1 = CD54) through a CD18/CD11a/b-dependent mechanism (Chapter 14 and 16).[4] Expression of selectins on endothelial cells is triggered by histamine and other mediators, whereas expression of ICAM-1 on endothelial cells is induced by various pro-inflammatory cytokines, such as tumor necrosis factor-α (TNF-α). As both histamine and TNF-α are produced and provided by (activated) mast cells, these cells are thought to play a crucial role in eosinophil recruitment in various allergic and other inflammatory reactions. However, the recruitment of eosinophils is a complex process involving many different mechanisms and molecules, such as E-selectin, endothelial-leukocyte adhesion molecule 1 (ELAM-1 = CD62E) or vascular cell-adhesion molecule-1 (VCAM-1 = CD106).[4] Recruitment of eosinophils is also mediated by adhesion to VCAM-1 via the β1 integrin very late activation antigen-4 (VLA-4 = CD49d/CD29), which is expressed by eosinophils but not by blood neutrophils.

Eosinophil migration is regulated by several different chemotactic factors, including various chemokines (SDF-1, eotaxins, IL-8, and others), the complement fragment C5a, PAF, and several eosinotropic cytokines, such as IL-5 or GM-CSF, which also prime eosinophils for enhanced migratory responses to PAF and IL-8. In addition, IL-2, leukotriene B_4, and the lymphocyte chemoattractant factor (LCF = IL-16) can induce eosinophil migration. At least for neoplastic eosinophils, a most potent chemoattractant appears to be SDF-1, a stromal cell-derived chemokine that binds to CXCR4 (CD184) on normal and neoplastic eosinophils.[10] Other potent chemoattractants for (neoplastic) eosinophils are the eotaxins (eotaxin-1, -2, -3) that bind to and signal through the chemokine receptor CCR3

(CD193; see Table 74.5).[9] Depending on the underlying disease, the cell type(s) involved, and the presence of comorbidities (triggering, e.g., local or systemic inflammation) all these chemotactic factors may act together to trigger eosinophil recruitment and accumulation in the affected (often inflamed) tissue sites. Likewise, in several reactive conditions, IL-5 and eotaxin may cooperate locally to promote eosinophil migration and tissue HE.

The primary source of eosinophil chemotactic factors often remains unknown. In many disease states accompanied by HE, eosinophil chemotactic factors may be produced by microenvironmental cells, including fibroblasts, endothelial cells, T-cells, macrophages, and mast cells. Several of these chemokines, like SDF-1, are produced by stromal cells in a paracrine fashion (see Chapter 12). For example, in neoplastic eosinophils, the *F/P* mutant triggers expression and release of oncostatin M (OSM), which in turn induces fibroblast and endothelial cell proliferation but also the expression and release of SDF-1 from these cells, thereby augmenting the accumulation of additional eosinophils.[11] In this regard, it is noteworthy that the SDF-1 receptor CXCR4 is not only expressed on mature eosinophils but also on hematopoietic stem cells and eosinophil-committed precursor cells. Depending on the type of underlying neoplasm, eosinophil chemotactic cytokines may also be produced in an autocrine manner.

Role of Mast Cells in Eosinophil Recruitment and Accumulation

In various inflammatory and allergic reactions, several different interactions between eosinophils and mast cells have been postulated (see Chapter 75). For example, mast cells provide the immediate stimuli upon activation to initiate allergic inflammation, resulting in eosinophil recruitment during the late phase following an allergen encounter. In addition, mast cells and eosinophils are often increased in numbers in allergic reactions, but also in nonallergic inflammatory conditions and even in neoplastic states. Both cell types express a similar profile of chemotactic receptors, such as CCR3, and both respond to eotaxins and RANTES (CCL5), leading to their recruitment into local tissue sites (see Chapter 12). Mast cells and eosinophils also interact with each other via cell–cell contact and through several different soluble mediators. Likewise, mast cell-derived heparin binds and stabilizes various chemokines, including the eotaxins. In addition, mast cells are a source of various cytokines involved in the regulation of eosinophil adhesion, migration, and function. As previously mentioned, mast cells express and release histamine and TNF-α, and thereby facilitate eosinophil recruitment. Mast cell proteases appear to have a dual action on eosinophil functions. Mast cell-derived chymase suppresses eosinophil apoptosis and induces the release of IL-6 and various chemokines (CXCL1, CXCL8, CCL2) from eosinophils. Beta-tryptase, on the other hand, can cleave eotaxin and RANTES, and thereby may limit eosinophil chemotaxis. Apart from these interactions, eosinophils and mast cells may sometimes also be derived from the same stem or progenitor cell compartment, and therefore may express the same driver mutant, which has been documented for cases of *F/P*+ chronic eosinophilic leukemia (CEL) with accompanying mast cell expansion, as well as for patients with *KIT* D816V+ systemic mastocytosis (SM) with concomitant HE (see Chapter 75). Therefore, mast cells and eosinophils may often appear as a dual-target cell population, both in reactive and neoplastic states, which is a critical point when considering the development of specific therapies. For example, simultaneous downregulation of eosinophil and mast cell activation might be achieved by certain inhibitory surface molecules, such as CD300a or Siglec-8.[12] Several other target receptors, such as Siglec-3 (CD33), are expressed on eosinophils, mast cells, and basophils. In patients with *F/P*+ neoplasms, imatinib can induce apoptosis in both eosinophils and mast cells, as both cell types express the mutant platelet-derived growth factor receptor (PDGFR) target in this neoplasm.

MONITORING OF EOSINOPHIL NUMBERS AND ACTIVITY IN HEALTH AND DISEASE

In the PB, eosinophils can easily be measured by microscopy or flow cytometry based on their characteristic side-scatter properties and their autofluorescence. In case of atypical (immature) cells or questionable results, immunophenotyping can be performed to confirm the presence of eosinophils. In tissue sections, the quantification of eosinophils is a more difficult task that makes routine clinical evaluations somewhat impractical. Alternative approaches such as analysis of tissue secretions from affected organs (e.g., bronchoalveolar lavage [BAL]) have been used with success in evaluating local eosinophil numbers and function in asthma. In addition to routine histochemical identification and enumeration of eosinophils and the immunochemical localization of secreted eosinophil granule cationic proteins in tissue biopsies, two other methods have been employed to demonstrate and monitor eosinophil activation and involvement: (1) the identification of activated eosinophils by staining with anti-ECP antibody EG2, recognizing a secreted (deglycosylated) form of the protein, and (2) measurement of eosinophil granule proteins, such as MBP or ECP by radioimmunoassay (RIA) or enzyme-linked immunosorbent assay in various body fluids, including serum, plasma, urine, sputum, nasal lavage, and BAL. Indeed, these antigens may serve as reliable biomarkers of eosinophil involvement and activation in allergic, parasitic, and inflammatory diseases. In addition, treatment responses can be demonstrated and measured with these assays.

ETIOLOGY AND PATHOBIOLOGY OF HYPEREOSINOPHILIA

In patients with documented HE, four etiologies have to be considered: (1) myeloid (and rarely myeloid/lymphoid) neoplasms where eosinophils are usually derived from neoplastic stem and progenitor cells, (2) lymphoid neoplasms or nonhematopoietic (solid) tumors where HE is a paraneoplastic phenomenon, (3) reactive conditions, such as an allergy, infection or an autoimmune disease where HE is a reactive process, and (4) rare syndromes accompanied by HE, including rare and inherited disorders (see Table 74.4A).[3] In patients with clonal (primary) HE, eosinophils and their progenitors often display rearrangements in *PDGFRA*, *PDGFRB*, or *FGFR1* genes.[13] Therefore, the World Health Organization (WHO) has employed these mutations as primary criteria to describe (classify) hematopoietic neoplasms accompanied by HE (Table 74.6).[14] The resulting "fusion proteins" act as prooncogenic drivers and are considered to contribute to cytokine-independent differentiation of eosinophil progenitor cells. The most frequently detected molecular abnormality is the *F/P* fusion gene, a mutant gene created by an 800-kb interstitial deletion on chromosome 4q12. The fusion gene is detectable by polymerase chain reaction (PCR) as well as by fluorescence in situ hybridization (FISH; deleted *CHIC2* gene) but cannot be detected by conventional karyotyping. However, conventional cytogenetics may reveal translocations, deletions, or inversions on chromosome 5q31-33, indicating rearrangements of *PDGFRB*, or abnormalities on chromosome band 8p11-12, indicating a rearrangement of the *FGFR1* gene. From a clinical point of view, it is of great importance to screen for these rearrangements in all patients using the correct techniques, as many of them, including *F/P*, are responsive to imatinib or other tyrosine kinase inhibitors (TKIs). However, clonal HE may also be caused by other mutations, including *BCR::ABL1*, rearranged *JAK2* (e.g., TK fusion partners *PCM1*, *BCR*, and *ETV6*) or *FLT3* (e.g., most common partner *ETV6*), or *KIT* D816V.[14] In a substantial subset of patients with MPN-eo, no mutation is found.

In paraneoplastic and reactive states, HE is usually triggered by eosinophilopoietic cytokines, including IL-5, IL-3, or GM-CSF. These cytokines, especially IL-5, may be detected in the serum of these

TABLE 74.6 **Molecular Classification of Eosinophil-Related Neoplasms Proposed by the WHO and Related Molecular and Cytogenetic Defects**[a]

1. Myeloid/lymphoid neoplasms with eosinophilia and tyrosine kinase gene fusions (MLN-TK):

   MLN-TK with *PDGFRA* rearrangement

   Most common variant: *FIP1L1::PDGFRA*$^{+}$ MLN-TK

   MLN-TK with *PDGFRB* rearrangement

   MLN-TK with *FGFR1* rearrangement

   MLN-TK with rearranged *JAK2*

   FLT3-rearranged MLN-TK

   ETV6::ABL1-rearranged MLN-TK

   MLN-TK with other fusion genes, such as *ETV6*::*FGFR2*, *ETV6*::*LYN*, or *ETV6*::*NTRK3*.
2. Chronic eosinophilic leukemia (CEL):

   BCR::*ABL1* and abnormalities in *PDGFRA*, *PDGFRB*, or *FGFR1* are excluded

   Other MPN-related molecular lesionsand MLN-TK-defining fusion genes are also excluded (CEL is now regarded as a separate form of MPN by the WHO)
3. WHO-defined myeloid neoplasms with HE, not included in "1" or "2":
   - a. Ph^{+} (*BCR::ABL1*$^{+}$) chronic myeloid leukemia (CML-eo)
   - b. *JAK2* V617F^{+} myeloproliferative neoplasms (MPN-eo)
   - c. *KIT* D816V^{+} systemic mastocytosis (SM-eo)
   - d. *CBFβ*-fusion gene-related acute myeloid leukemia (AML-eo/M4-eo)
   - e. Myelodysplastic syndromes with HE (MDS-eo)
   - f. Other WHO-defined myeloid neoplasms with HE

aCML, Atypical chronic myeloid leukemia; *CEL*, chronic eosinophilic leukemia; *CMML*, chronic myelomonocytic leukemia; *FGFR*, fibroblast growth factor receptor; *HE*, hypereosinophilia; *MDS*, myelodysplastic syndrome; *MLN-TK*, myeloid/lymphoid neoplasms with eosinophilia and tyrosine kinase gene fusions; *MPN*, myeloproliferative neoplasm; *PDGFR*, platelet-derived growth factor receptor; *Ph+*, Philadelphia chromosome positive; *SM*, systemic mastocytosis; *WHO*, World Health Organisation.

[a]The table refers to the WHO classification of eosinophil neoplasm.[14]

patients and are considered to be produced by activated T cells or other activated immune cells. In a few patients with HE and HES, activated (clonal) T cells are detectable by phenotyping and PCR, but no underlying lymphoma or other underlying condition is found. In these cases, the lymphoid variant of HES (HES_L) is diagnosed.[15] In some of these patients, an overt T-cell lymphoma or Sézary syndrome may develop in the follow-up. A number of different reactive conditions and disorders, including helminth infections, fungal infections, autoimmune disorders, allergies, or drug reactions, can lead to reactive HE and reactive HES (HES_R). These conditions are listed in Table 74.2.

Pathogenesis of Eosinophil-Associated End-Organ Damage in Patients With Hypereosinophilic Syndrome

Regardless of the underlying etiology (neoplastic or reactive), sustained HE may lead to typical end-organ damage defined as HES. Even in patients with idiopathic HE, such organ damage may occur and is then called *idiopathic HES* (HES_I).[3] However, not all patients presenting with HE develop organ damage even if followed over a longer time period. For example, patients with an underlying allergic disease usually fail to develop the organ damage seen in patients with typical HES. When neither an underlying disease nor HE-related organ damage is found, the diagnosis HE of undetermined significance (HE_US) is established.[3] In general, the risk of HES is lower in reactive forms of HE, especially when the underlying disease can be treated successfully. Correspondingly, IL-5 transgenic mice with massive HE do not develop significant end-organ damage, suggesting that other factors (in addition to IL-5) are likely necessary for the occurrence of an HE-related organ damage. In patients with an underlying MPN or other underlying myeloid neoplasm, the risk of HE-related organ damage (HES) is relatively high. A particularly high risk is found in patients with mutations in *PDGFR* genes. Likewise, most untreated patients with *F/P*+ MPN-eo or CEL may develop HES with cardiac involvement over time. Additional risk factors may also contribute to the development of HES in these patients, including, among others, an additional prothrombophilic state, late detection of the disease, and late initiation of specific (anti-CEL) therapy. There may also be a certain genetic predisposition for early occurrence of tissue HE in patients with *F/P*+ CEL (*F/P*+ MPN-eo). In particular, the severity (extent) of tissue HE seems to correlate with a polymorphic variant (SNP in the 5′-UTR) in the *IL-5RA* gene.[16] However, it remains unclear whether this SNP predisposes to HES development or progression, and thus is relevant clinically. Today, the general recommendation is to initiate therapy with imatinib early in all *F/P*+ patients, regardless of genetic, molecular or other factors, in order to prevent any HES occurrence and to avoid disease progression (to acute leukemia).

A number of different organ systems are affected in patients with HES.[3] The most common manifestations are summarized in Table 74.7. Although multiple organ systems are involved and the manifestation patterns are quite complex with varying courses and outcomes, some common pathogenetic factors have been described. One common feature is the mobilization of the tissue microenvironment by eosinophil-derived mediators and cytokines, which leads to tissue remodeling, fibrosis, and increased angiogenesis.[3,7,17] Another common factor is tissue inflammation, which is typically triggered by eosinophil-derived cytokines and chemokines.[3,17] Finally, HE-related organopathies may often result from direct cytotoxic damage that is induced by the various toxic mediators produced and released by (reactive and neoplastic) eosinophils.[3,17] With regard to thromboembolic events, several different eosinophil-derived mediators have been implicated, including TNF-α, plasminogen activator inhibitors (PAIs), and eosinophil-derived DNA traps (see Table 74.1).[2,17] In addition, ECPs have the capacity to alter thrombomodulin activity. A number of different compounds produced by eosinophils, including cationic proteins and various cytokines, may induce fibrosis. Among these cytokines, OSM may play a particular role as a HES-related profibrogenic cytokine.[11] HE-related neoangiogenesis may be triggered by IL-8, OSM, and vascular endothelial growth factor (VEGF). All these cytokines are produced and secreted by normal/reactive and also by neoplastic eosinophils. However, neoplastic eosinophils produce some of these cytokines in excess over their normal counterparts. For example, *F/P*+ eosinophils express and release huge amounts of OSM, IL-8, and VEGF.[11] The F/P mutant induces the production and secretion of these mediators in neoplastic cells in a STAT5-dependent manner. Concerning the mobilization of the microenvironment in various organs in patients with HES, a most critical *F/P* target gene may be *OSM*. Notably, OSM initiates not only fibrosis and angiogenesis by triggering fibroblast proliferation and tube formation in endothelial cells, but also by inducing the production of multiple cytokines and chemokines in stromal cells. Among these mediators are IL-8, SDF-1, and other chemotactic factors that can recruit additional CXCR4+ precursor cells and eosinophils to local tissue sites.[11]

An unresolved question is why HE-related fibrosis and thrombosis affect certain tissues and organs, including the heart and lungs. One explanation may be that eosinophils invade heart and lung tissues via "physiologic" routes, which may not be the case in other MPNs where HE usually does not occur. An additional explanation may be that eosinophil-derived mediators are toxic to certain (tissue-specific) cell types such as cardiomyocytes. Indeed, as noted earlier, eosinophils express a number of different cationic proteins capable of inducing endothelial and endocardial damage and neurotoxicity. In addition, the eosinophil has the capacity to generate reactive oxidative species that can augment tissue damage.

DEFINITION AND CLASSIFICATION OF HYPEREOSINOPHILIA AND HYPEREOSINOPHILIC SYNDROME

The term HES was initially proposed for a syndrome characterized by idiopathic HE and HE-related organ damage, as well as by exclusion of various conditions and diseases that are typically accompanied by HE. More recently, the definition of HES has been refined as any type of HE (not just idiopathic) associated with typical HE-related end-organ damage.[3] According to the proposal of an international working group on eosinophil disorders (ICOG-EO), the term HES should be reserved for clinical syndromes fulfilling HES criteria, but not for underlying (hematologic) malignancies or immunological disorders presenting with HE.[3] In other words, the diagnosis HES must prompt the physician to search for (detect) an underlying (HES-triggering) disease. Accordingly, the final diagnosis is either idiopathic HES or HES based on a recognized underlying disorder, and both need to be documented in the final diagnosis. In previous WHO classifications, the term HES was sometimes used as a synonym of CEL, and sometimes to discriminate CEL from other less well-defined myeloid neoplasms with HE. However, in the 2008 edition of the WHO monograph, the term HES was no longer recommended as a synonym of WHO-defined neoplasms, a distinction that is in agreement with the proposal of the ICON group and the proposal of the ICOG-EO group.[3]

Definition of Hypereosinophilia

HE is currently defined as a persistent, microscopically confirmed increase in PB eosinophils to $\geq 1.5 \times 10^9$/L. In previous definitions, persistent eosinophilia over 6 months was required to establish the diagnosis HE. However, based on improved diagnostics and treatment, and the necessity to introduce such treatment rapidly to avoid organ damage, the proposed definition of HE has been revised to a 4-week observation interval by the ICOG-EO group.[3] The term "tissue HE" has also been proposed by several experts, and it may be useful to apply it in certain conditions, especially in the context of (to demonstrate) HE-related organ damage (HES). However, isolated tissue HE (without blood HE) is rare, and the documentation of tissue HE often requires special immunostains directed against eosinophil granule proteins.[7] Therefore, the presence of tissue HE is often overlooked or is not documented, and PB HE clearly remains the key diagnostic marker in daily practice. In some of these patients, criteria for blood HE are not met, but molecular and clinical signs are strongly indicative of a particular eosinophil disorder with or without accompanying HES. These patients should be followed closely, as they may progress to an overt eosinophil disease (neoplasm) over time. The same holds true for WHO-based neoplasms presenting with *PDGFR* or *FGFR1* fusion genes without overt HE.[14] In fact, many patients with *FGFR1*-rearranged neoplasms do not have eosinophilia at presentation.

Diagnostic Algorithm

When arriving at the provisional pre-diagnostic "checkpoint" HE, two critical questions have to be addressed in order to approach to a final diagnosis: (1) is there any underlying disease or condition triggering HE? *and* (2) are there clinical signs and symptoms or laboratory abnormalities that point to the presence of HE-induced organ damage, so that the diagnosis of HES can be established? For example, the hematologic work-up in a patient with HE revealed CEL, and staging investigations showed endocardial thrombus formation: the final diagnosis in this patient is CEL with concomitant primary HES (HES_N). A diagnostic algorithm is shown in Fig. 74.3. In patients with typical HES and typical clinical manifestation, histopathologic evaluation is generally not warranted to confirm the presence of tissue HE. However, in patients with rare or atypical manifestations, such as renal failure, isolated myocarditis or bloody diarrhea, a tissue biopsy is required to document the presence of tissue HE and to confirm HE-induced organ damage, so that the diagnosis HES can be established. The demonstration of extensive extracellular deposition of eosinophil-derived proteins supports the conclusion the organ damage is "HE-related."[7]

Figure 74.3 DIAGNOSTIC ALGORITHM FOR PATIENTS WITH EOSINOPHIL DISORDERS. The first important step in the algorithm is to confirm the presence of HE, defined by a persistent (>4 weeks) increase in eosinophils above 1500/µL blood. The next important question is whether HE is reactive (HE$_R$) or neoplastic (clonal = HE$_N$) in nature. In patients with HE$_N$, WHO criteria should be applied in order to define the underlying molecular lesion and the WHO category of disease. *In patients with HEN associated with oncogenic fusion genes involving, for example, PDGFRs, the WHO diagnosis is: myeloid/lymphoid neoplasm with eosinophilia and tyrosine kinase gene fusions (MLN-TK). In addition, morphologic and histopathologic criteria are used to arrive at a final diagnosis regarding the underlying disease. In patients with HE$_R$, an underlying disease must also be defined. In both groups of patients, the next important question is whether (or not) HE-related organ damage is present. If such pathological changes (tissue damage) are found, it is appropriate to diagnose a HES. According to the underlying etiology (disease), HES is classified again into HES$_R$ and HES$_N$. In some patients with HES, a clonal T-cell population (but no overt lymphoma) is detected. In these patients, the HES$_L$ variant is diagnosed. If no clonal T cells and no underlying reactive or neoplastic condition is detected in a patient with HES, the (provisional) diagnosis of an HES$_I$ is established. If no underlying disease and no HES are detected, the patient has HE$_{US}$ by definition. Familial cases of HE or HES are very rare, and the same holds true for hereditary syndromes and mono-organ syndromes accompanied by HE. *HE*, Hypereosinophilia; *HES*, hypereosinophilic syndrome; *HES$_F$*, familial HES; *HES$_I$*, idiopathic HES; *HES$_L$*, lymphoid variant of HES; *HES$_N$*, primary (neoplastic) HES; *HES$_R$*, reactive HES; *HE$_{US}$*, HE of undermined (unknown) significance; *WHO*, World Health Organization.

Classification of Hypereosinophilia and Hypereosinophilic Syndrome

The classification of HE and HES is essentially based on the related disease and underlying etiology. Accordingly, HE and HES are both divided into a familial variant (HE$_F$, HES$_F$), a primary/neoplastic form (HE$_N$, HES$_N$), and reactive entities (HE$_R$, HES$_R$; see Table 74.3).[3] In a smaller fraction of patients, the etiology of HE and HES remains uncertain. In other rare cases, two different causative factors are detected. When the etiology of HE remains uncertain after a thorough investigation and appropriate testing and no organ damage is detected, the final diagnosis is HE of uncertain (undetermined) significance (HE$_{US}$); and if HES is diagnosed, but no underlying disease is detected, the final diagnosis is idiopathic HES (HES$_I$).[3]

In general, four major groups of underlying disorders (conditions) have to be considered in HE (HES) patients: (1) myeloid (and rarely myeloid/lymphoid) neoplasms including eosinophilic leukemia (HE$_N$; HES$_N$), (2) lymphoid or nonhematopoietic neoplasms (paraneoplastic HE, a special variant of HE$_R$), (3) common allergic, reactive, or immunologic conditions (HE$_R$ and HES$_R$), and (4) clinically defined, rare syndromes and conditions accompanied by HE, including rare inherited disorders and organ-restricted inflammatory diseases with tissue HE.[3,17] Overall, the classification of HE/HES remains an important step in the diagnostic algorithm (see Fig. 74.3). Using generally accepted criteria and parameters, this approach should lead to a final diagnosis concerning the presence or absence of HES and the presence or absence of an underlying disease.

CLINICAL MANIFESTATIONS OF HYPEREOSINOPHILIC SYNDROME IN VARIOUS ORGAN SYSTEMS AND DIFFERENTIAL DIAGNOSIS

Depending on the type of disease and other factors, a number of different organ systems may be involved in patients with HES. The most commonly involved organs are the skin, lungs, GI tract, heart, and the CNS (see Table 74.7). In some patients, the relationship between HE and the typical clinical signs and symptoms are pathognomonic, whereas in other cases a tissue biopsy may be required to confirm HE-related organopathy.[3,17]

Cardiac Manifestations in Patients With Hypereosinophilic Syndrome

Prior to the advent of improved diagnostics and management, and novel therapeutic approaches, cardiac disease was the leading cause of morbidity and mortality in patients with HES. Endomyocardial thrombosis and fibrosis are often documented in HES_N, particularly in association with the *F/P* fusion gene, but are also seen in other variants of HES, including tropical forms induced by (persistent) parasitic infections and other reactive forms of HES. A thorough cardiac evaluation including an ECG and echocardiogram is mandatory in all patients with HE, and cardiac magnetic resonance imaging (MRI) may be helpful in distinguishing a HE-related cardiac disease from other etiologies.[3,17] Troponin levels and B-type natriuretic peptide levels may also be helpful parameters. An endomyocardial biopsy may be required in some of these patients in order to establish the definitive diagnosis, but biopsies are usually not performed in daily practice.

The cardiac damage seen in HES, usually progresses from early necrotic changes to thrombosis and fibrosis. The presence of eosinophils in the myocardium is always abnormal and highly suggestive of eosinophil-mediated organopathy. Identical forms of cardiac pathologies can develop in patients with HES forms of diverse etiologies, including tropical eosinophilias caused by parasitic infections, drug reactions, eosinophilic leukemias, MPN-eo, solid tumors, CSS and lymphomas. However, some of these patients may never go on to develop cardiac involvement, suggesting that disease manifestation likely involves as yet undefined factors required for HE-related tissue damage. The histopathology of cardiac involvement in HES is well characterized and can evolve through three defined stages in which eosinophils and eosinophil-derived mediators may be involved. These include (1) an initial acute necrotic stage of short duration (a few weeks) involving active endomyocarditis, (2) a later thrombotic stage (several months) with mural thrombus formation over endocardial lesions, and (3) a late fibrotic stage (after approximately 2 years of illness) with development of endomyocardial fibrosis. The early necrotic stage of cardiac disease is usually not recognized clinically. Echocardiography and angiography may fail to detect abnormalities at this early stage because ventricular thickening has not yet occurred and endomyocardial biopsies, generally from the right ventricle, are required to make the correct diagnosis of cardiac involvement. In the second stage, thrombi form over the damaged endocardium in either of the ventricles or the atrium, generally with sparing of the aortic and pulmonary valves. Progressive scarring at sites of mural thrombus formation ultimately leads to the late fibrotic stage, with endomyocardial fibrosis resulting in a restrictive cardiomyopathy and mitral or/and tricuspid valve regurgitation (see Table 74.7). The more common clinical manifestations in the later progressive stages of endomyocardial fibrosis include dyspnea, chest pain, signs of left or right ventricular congestive heart failure, or both, murmurs from mitral valve regurgitation, cardiomegaly, and T-wave inversions. Most patients who progress to this stage of HES-related cardiopathy have echocardiographic abnormalities, with thickening of the left ventricular wall being a common finding. However, electrocardiographic and MRI changes in these patients are not specific to HES. Differential diagnoses include infectious etiologies (endomyocarditis), autoimmune disorders such as rheumatoid arthritis, Marfan syndrome, thyroid disorders, and ischemic heart disease. Although various imaging techniques are helpful in evaluating HES-related cardiopathy, endomyocardial biopsy from the right and left ventricle remains a gold standard in diagnostic evaluation in patients with HE-related cardiopathy.

Pulmonary Manifestations

Approximately 50% of HES patients have pulmonary involvement, with the most common symptom being a chronic and persistent (nonproductive) cough. In order to confirm pulmonary manifestation in HES, a number of studies may be helpful, including pulmonary function tests, chest radiography and/or CT scan, bronchoscopy with BAL studies, and a tissue biopsy if necessary. The physiologic basis of pulmonary involvement in HES remains unknown. As in the heart, several different eosinophil-derived (cytotoxic and stroma-targeting) mediators and cytokines may act together to induce tissue damage and tissue remodeling, as well as fibrosis and thrombosis. Some of the pulmonary features may also reflect changes secondary to congestive heart failure. Although bronchospasm has been noted in some patients, full-blown asthma is rare in HES patients. Transudative pleural effusions are mostly seen in patients with frank congestive heart failure. In contrast to chronic eosinophilic pneumonia, the pulmonary infiltrates seen in HES patients are either diffuse or focal, without any preference for particular regions of the lung. Pulmonary infiltrates in HES often clear with prednisone treatment, but not all patients are responders. Pulmonary fibrosis is rare but can develop in patients with endomyocardial fibrosis. The differential diagnosis of HES_R with pulmonary involvement includes drug allergy, CSS, chronic eosinophilic pneumonia, severe allergic bronchial asthma with eosinophilia, allergic bronchopulmonary aspergillosis, and other eosinophilic lung infections.

Cutaneous Manifestations

The skin is frequently involved in HES, with cutaneous lesions present in over 50% of all cases. In these patients, the cutaneous lesions fall into three categories: (1) angioedematous and urticarial lesions; (2) erythematous, pruritic papules and nodules; and (3) mucosal ulcerations (see Table 74.7).[18] Patients with angioedema and urticaria are more likely to have a benign disease that is responsive to corticosteroids, without the development of cardiac or neurologic symptoms. A subgroup of patients with cyclic angioedema and eosinophilia are considered to have a syndrome (episodic angioedema with eosinophilia = Gleich syndrome) that is distinct from classical HES. These patients have a disorder with recurrent attacks of angioedema and urticaria accompanied by fever and weight gain. In HES patients with papular or nodular lesions, dermal biopsies usually show mixed cellular infiltrates, including eosinophils, without signs of vasculitis. Perivascular eosinophilic infiltrates are also found in these lesions. In a group of HES patients with skin involvement, the erythematous pruritic eruptions and indurated papules and nodules may respond to psoralen and ultraviolet light A. In other patients with HES-associated pruritus, the nodular lesions may respond to dapsone and corticosteroids. Oral sodium cromoglycate (cromolyn sodium), administered before meals, has also been reported to be efficacious, although neither dapsone nor cromolyn is able to reduce eosinophil counts in the blood. Severe and sometimes incapacitating mucocutaneous ulcerations may be a prodrome to HES and indicate a subset of HES patients with a poor prognosis. These lesions can appear at multiple sites, including the mouth, nose, pharynx, penis, esophagus, stomach, and anus. The lesions can flare up independently of other clinical manifestations of HES. Biopsies of the ulcerative lesions usually show mixed cellular infiltrates, without a predominance of eosinophils or any evidence of vasculitis or microthrombi. These ulcers are usually resistant to treatment with corticosteroids, colchicine, and hydroxyurea (HU), but they often respond to interferon-α (IFN-α), with complete and durable remissions in most patients. There are a number of additional diagnoses that have to be excluded in HES patients with suspected skin involvement, including drug reactions, local infections, and atopic eczema.

Neurologic Manifestations

Neurologic involvement is quite common in HES, affecting approximately 50% of all patients. In these cases, three different types of manifestations have been described. The first form of neurologic involvement is caused by thromboemboli, which may originate from intracardiac thrombi in the left ventricle but may also develop locally in cerebral vessels. Some of these thromboembolic episodes may occur before an overt cardiac manifestation has been documented. Patients with thrombotic complications may experience embolic strokes or transient ischemic attacks that may be multiple and recurrent, and these episodes may occur even though the patient is adequately anticoagulated. The second type of neurologic manifestation is primary diffuse CNS involvement. These patients may variably exhibit changes in behavior, confusion, ataxia, and loss of memory. The third neurologic abnormality noted in HES is the development of peripheral neuropathy, which can occur in approximately 50% of HES patients exhibiting neurologic involvement. This includes symmetric or asymmetric sensory polyneuropathies, including sensory deficits, painful paresthesias, or mixed sensory and motor defects (see Table 74.7). These neuropathies may improve with corticosteroid administration or other treatments and may be stable or continue to progress despite therapy, or may improve or even resolve with time. The histopathology of the involved nerves usually shows varying degrees of axonal loss, without evidence of vasculitis or direct or peripheral eosinophil infiltration. Whether EDN and/or ECP, known to cause neurotoxicity in experimental animals, are involved in the development of neuropathies in HES remains unknown. Based on immunohistochemical studies, these proteins are not detectable at the sites of ongoing neuropathology in HES patients. Overall, the etiology of HES-related neuropathy remains poorly defined. Differential diagnoses of HES-related neuropathies are manifold and include, among others, neurodegenerative disorders, multiple sclerosis, and CNS infections.

Gastrointestinal Manifestations

Compared to lung or skin, GI tract involvement is less common in patients with HES. Although any form of HES can present with GI tract manifestation, GI tract symptoms are mostly recorded in patients with HES_R or the idiopathic form of HES. In these patients, a wide variety of symptoms and findings have been described, including abdominal pain, vomiting, diarrhea, or ulcerative disease, but also ascites or an overt colitis (see Table 74.7). These patients may also report bloody diarrhea and weight loss. Histologically, GI tract involvement with HES is characterized by an infiltration of the mucosa and submucosa with eosinophils. Immunohistochemical examination may reveal a huge infiltration with eosinophils as well as extensive deposition of extracellular eosinophil proteins in the gastric mucosa. In most patients with reactive HES, the GI tract disease component responds to treatment with oral corticosteroids. Differential diagnoses of GI tract involvement with HES include localized (organ-restricted) inflammatory disorders, such as eosinophilic esophagitis, eosinophilic gastroenteritis, eosinophilic colitis, autoimmune diseases, chronic inflammatory bowel disease, GI infections, GI tract lymphomas, and GI tract involvement in patients with SM. Especially in patients with SM, the underlying disease is often overlooked, since neoplastic mast cells are outnumbered by the infiltrating eosinophils. In these cases, the use of mast cell-related immunohistochemical markers, including tryptase and KIT (CD117), and CD25, is recommended to diagnose an underlying SM.

Hematologic Manifestations and Bone Marrow Involvement

In HES patients suffering from an underlying myeloid neoplasm (HE_N, HES_N), the BM is almost always involved. In these patients, the BM is often hypercellular and shows a substantial increase in eosinophil numbers. In addition, alterations in the BM microenvironment, including increased microvessel density and BM fibrosis, is usually detected in these patients. Depending on the underlying neoplasm, other hematopoietic lineages may also be affected and may show typical morphological or phenotypic aberrations. Depending on the underlying neoplasm, eosinophils may be mature or (rather) immature cells (see Fig. 74.2B and C). The BM is also affected in patients with reactive or idiopathic HES. However, in these patients, eosinophils are usually mature cells and no major alterations in the BM microenvironment or abnormalities in other hematopoietic lineages are found.

Apart from eosinophilic leukemia, a number of different underlying BM neoplasms may be identified, such as an MPN, myelodysplastic syndrome (MDS), MDS/MPN overlap syndrome, acute myeloid leukemia (AML), or, rarely, a lymphoid malignancy.[17] In these patients, various blood count abnormalities may be present, such as neutrophilia, monocytosis, basophilia, thrombocytosis, a left-shifted white blood count, or an increase in blasts. In some cases, anemia or/and thrombocytopenia with or without increased blast cells or dysplasia is found, consistent with the diagnosis of an overt MDS, an MDS/MPN overlap syndrome, or AML. In rare cases, a stem cell neoplasm with involvement of both the myeloid and lymphoid lineage is detected. In these patients, an *FGFR1*-rearranged neoplasm (historically referred to as 8p11 myeloproliferative syndrome or stem cell leukemia/lymphoma) may be diagnosed.[13] The prognosis is poor in these patients as the *FGFR1*-mutated cells have historically been resistant to AML- or ALL induction-type combination-chemotherapy or nonselective TKIs with anti-FGFR activity. More recently, a number of more potent and rather selective FGFR inhibitors, such as pemigatinib, have demonstrated considerable efficacy with hematologic and cytogenetic remissions in patients with *FGFR1*-rearranged neoplasms.

In some patients with CEL, a massive leukocytosis is found. In these cases, eosinophilia of more than 90% may be seen, and total leukocyte counts may exceed 50 × 10^9/L or even 100 × 10^9/L[3].[3,17] Extremely high leukocyte (eosinophil) counts are more commonly seen in patients with HES_N in the context of CEL.[3] Blood smears from patients with HES_R and HES_I generally show more or less normal, mature eosinophil morphologies, including typical bilobed nuclei and granule-rich cytoplasm. However, hypodense eosinophils and eosinophilic precursor cells may also be observed, although less commonly, and eosinophils may also exhibit morphologic abnormalities, including nuclear hypersegmentation, decreased size and/or numbers of secondary granules, and cytoplasmic vacuolization. BM mast cell numbers, often in an interstitial pattern, may be increased in HES patients. This is often associated with an increased level of serum tryptase, especially in *F/P*+ cases, where these cells usually belong to the neoplastic clone. The presence of myeloblasts and/or dysplastic findings in the PB may suggest the presence of AML or MDS and is thus associated with a more unfavorable prognosis. Splenomegaly is present in a substantial subset of patients with HES, mostly in those with an underlying myeloid neoplasm, but sometimes also in cases with a reactive form of HES or idiopathic HES. In patients with markedly enlarged spleens, hypersplenism may develop and may contribute to thrombocytopenia and anemia. In these patients, splenic pain induced by capsular distention or infarction are well-known complications.

Underlying Hematologic Disorders and Differential Diagnoses

Although various hematologic neoplasms may be accompanied by eosinophilia, only a few of these are associated with persistent HE (HE_N) and HE-related organ damage (= HES_N). For example, mild-to-moderate eosinophilia may be detected in Philadelphia chromosome-positive (Ph^+; BCR::ABL1$^+$) chronic myeloid leukemia (CML) and various Ph^- MPNs, but marked HE is unusual and HES is rarely found in these patients. However, in a few patients with CML or MPNs, excessive HE may develop (see Chapter 69). In these patients, HE is usually responsive to BCR::ABL1 kinase inhibitors in CML, and to conventional cytostatic drugs, such as HU or IFN-α, in a patient with an MPN. In a few myeloid neoplasms substantial or even excessive HE is a typical finding. Based on the proposal of an international consensus group (ICOG-EO) these malignancies include the rare variant of acute eosinophilic leukemia (AEL), the more common variant of CEL that is often associated with a *F/P* fusion gene, and other forms or CEL or MPN-eo with rearrangements involving *PDGFRA*, *PDGFRB*, or *FGFR1*.[3,13] Other patients with CEL may fulfill WHO criteria of CEL, listed as WHO MPN (see Table 74.6).[3,14] Rarely, HE_N is found in patients with MDS. In most cases with dysplastic BM and HE, however, additional signs of myeloproliferation are found, consistent with a diagnosis of a MDS/MPN overlap syndrome or frank MPN (see Chapter 73).[3] Another myeloid neoplasm that is often accompanied by HE is SM (see Chapter 75).[19] In fact, HE_N is frequently seen in patients with advanced SM, including aggressive SM and mast cell leukemia (see Table 74.6). Most of these patients develop HE without HE-related organ damage (HES). In rare cases, lymphoid neoplasms may also present with HE. In these patients, a T-cell lymphoma is most commonly detected as underlying disease during initial staging investigations or during follow-up. In most patients with T-cell lymphomas accompanied by HE, eosinophils are nonclonal cells. By contrast, in patients with fusions involving *FGFR1*, where stem cells are considered to give rise to malignant cells, both eosinophils and lymphocytes are clonally involved. The prognosis in these patients has been historically poor.

Several different proposals to classify eosinophil neoplasms have been presented in the past.[3,14,20] The WHO has classified eosinophil-related disorders according to the presence of certain molecular lesions, including abnormalities in the *PDGFR* or *FGFR* genes or *PCM1::JAK2* (see Table 74.6).[14] In the 2022 update, the WHO has included additional fusion genes in this category, whihc is now termed MLN-TK (see Table 74.6). The advantage of this approach is that it refers to molecular targets of therapy. As a result, therapeutic decisions may be directly based on a WHO-based diagnosis. However, independent of the clinical presentation and markers, the WHO classification has to be complemented by a final histopathologic diagnosis, which in turn is based on thorough morphologic, histopathologic, and immunohistochemical studies of the BM.[3,17] Based on a proposal of the ICOG-EO group,[3] the following underlying neoplasms have to be delineated (Table 74.8A).

Acute Eosinophilic Leukemia

This type of leukemia is defined by HE, more than 19% (≥20%) myeloblasts and greater than 29% (≥30%) eosinophils in BM smears (see Table 74.8A).[3] Other classical types of MPNs and CML must be excluded. AEL is an extremely rare disease. Eosinophils in these patients may be quite immature, hypogranulated cells, or represent a mixture of mature and immature eosinophils. In some of these patients, a prodrome of MDS or MPN without HE occurs. In addition, *F/P*+ patients with CEL or *F/P*+ MPN-eo may progress to AEL during their terminal phase. However, (other) recurrent cytogenetic or molecular marker have not been identified in AEL patients. The clinical course in AEL is unfavorable. Chemotherapy and stem cell transplantation are usually recommended. Major differential diagnoses include AML M4-eo with inv16, CEL with signs of progression, and SM-associated with another hematolological malignancy (AHN)-eo (e.g., SM-AML-eo).

TABLE 74.8A **Histopathologic Classification and Criteria of Eosinophilic Leukemias and Other Myeloid Neoplasms Presenting With Hypereosinophilia**

Neoplasm(s)	Abbreviation	Definition/Criteria
i. Acute eosinophilic leukemia	AEL	HE and eosinophils ≥30% and myeloblasts ≥20%
ii. Chronic eosinophilic leukemia	CEL[a]	HE and eosinophils ≥30% and myeloblasts <20% and no underlying stem cell-, myeloid or lymphoid neoplasm found
iii. Other myeloid neoplasm (MN) or stem cell neoplasm with HE: MPN-eo, MDS-eo, SM-eo,	MN-eo	MN or stem cell neoplasm by WHO or FAB criteria and HE, but eosinophils <30%

The histopathological classification of eosinophil disorders assists the WHO-based delineation of neoplasms presenting with eosinophilia (HE). In a first step, the diagnosis is based on the WHO definition as molecular and cytogenetic abnormalities are examined. In a second step, the final histomorphologically defined diagnosis needs to be established using the criteria of the ICOG-EO depicted in this table.[3] Values for eosinophils and blast cells refer to the bone marrow smear. In rare cases (acute leukemia), eosinophils may be quite immature and may escape conventional morphological identification. In these cases, immunophenotyping or electron microscopy may be required.

AEL, Acute eosinophilic leukemia; *CEL*, chronic eosinophilic leukemia; *FAB*, French–American–British Cooperative Study Group; *HE*, hypereosinophilia; *ICOG-EO*, International Cooperative Study Group on Eosinophil Disorders *MDS*, myelodysplastic syndromes; *MPN*, myeloproliferative neoplasm; *WHO*, World Health Organization.

[a] In order to diagnose CEL, the following cytogenetic and molecular defects have to be excluded as primary reason of HE: *BCR::ABL1*, inv(16), t(16;16), *JAK2* V617F.

Chronic Eosinophilic Leukemia

In patients with CEL, eosinophils comprise ≥30% of all nucleated BM cells and/or blood leukocytes. As per ICOG-EO definition, patients with CEL have overt HE_N and less than 20% myeloblasts in their BM and/or blood smears (see Table 74.8A).[3] Usually, blast counts are below 5%. In most patients, neoplastic cells exhibit rearrangements (mutations) in genes coding for *PDGFRA*, *PDGFRB*, or *FGFR1*. Therefore, most patients also fit into the WHO category of "myeloid/lymphoid neoplasm with eosinophilia and tyrosine kinase gene fusions (MLN-TK)." Other BM neoplasms need to be excluded by BM examination. Major differential diagnoses include AEL, MPN-eo, MPN/MDS-eo, SM-eo, SM-AHN-eo, and reactive forms of HE/HES. Progression from CEL to AEL is an extremely rare event. However, in untreated patients with *PDGFR* mutations and those with *FGFR1* mutations, progression of CEL to AEL or even AML may occur. The prognosis in CEL depends largely on the molecular lesions detected. In patients with CEL exhibiting *PDGFR* mutations, the prognosis is excellent, as in most cases the disease responds to imatinib. By contrast, in patients with *FGFR1* mutations, the diagnosis is dismal, even when treated with chemotherapy and early allogeneic hematopoietic stem cell transplantation (HSCT) should be considered. However, more recently, pemigatinib, a potent and selective small molecule inhibitor of the FGFR, has been reported to be efficacious in patients with *FGFR1*-rearranged myeloid/lymphoid neoplasms. Pemigatinib is a selective and potent inhibitor of FGFR1–3 approved in the United States, EU, and Japan for the treatment of adults with previously treated, unresectable, locally advanced, or metastatic cholangiocarcinoma with a *FGFR2* fusion or other rearrangement.

MPN-eo, MPN/MDS-eo, MDS-eo, and SM-eo

The exact nomenclature of myeloid or mast cell neoplasms with marked eosinophilia (HE) is still under debate.[20] The ICOG-EO group has proposed the use of the appendix "-eo" for patients in whom HE_N is detected but criteria of AEL or CEL are not met.[3] In fact, in these patients an underlying MPN, MPN/MDS, MDS, or SM is diagnosed, and HE is present. However, eosinophils comprise less than 30% of all nucleated BM and PB leukocytes. In patients with MPN-eo, MPN/MDS-eo, or MDS-eo, HE may be detected at diagnosis or may develop during the follow-up period. In a small group of patients, mutant forms of *PDGFR*s or the *FGFR* are found. In other patients, karyotype abnormalities are detected, but *PDGFR* or *FGFR* mutants are not found. The molecular mechanisms underlying HE development in these patients usually remains unknown. Differential diagnoses include Ph^+ CML, CEL, AEL, and SM-AHN-eo (see Chapter 75). The overall prognosis depends on the underlying neoplasm, especially on blast cell counts, karyotypes and the expression of *PDGFR* or *FGFR1* mutants. Therefore it is important to apply all markers and diagnostic tests in order to define the exact diagnosis. In MDS and MPN/MDS, the presence of eosinophilia is an independent prognostic factor and indicative of poor survival, especially when HE is accompanied by blood basophilia.[21] Treatment of patients depends largely on the type of underlying malignancy, but also on the presence of distinct molecular lesions and targets. In advanced stages of the disease, a complex karyotype and complex mutational patterns are often found. These patients are candidates for intensive treatment, including HSCT.

Lymphoid Neoplasms, Lymphomas

A number of different lymphomas may produce eosinophilia, mostly through the generation of eosinophilopoietic cytokines in neoplastic cells. An exception is the 8p11 myeloproliferative syndrome (*FGFR1*-rearranged neoplasm), where eosinophils are derived from the malignant clone even if the primary tumor was classified as a lymphoma.[13] Most lymphoma patients with paracrine HE suffer from a (peripheral) T-cell non-Hodgkin lymphoma (NHL) (see Chapter 89). In these patients, clonal T cells are considered to represent the primary source of eosinophilopoietic cytokines, such as IL-5. A prephase of HES$_{L}$ or HE$_{US}$ may be present. The prognosis of patients with peripheral T-cell NHLs is poor, even when treated with chemotherapy, such as cyclophosphamide, hydroxydaunomycin, vincristine, and prednisone. Therefore allogeneic HSCT is usually recommended for these patients, provided that the patient has an acceptable performance status and a suitable donor is available, and the same holds true for lymphoma patients presenting with an *FGFR1* rearrangement. Relapsing disease after HSCT has an extremely poor outcome. These patients are treated with investigational agents and palliative cytoreduction. A summary of BM neoplasms presenting with HE is provided in Table 74.8B.

TABLE 74.8B Hematopoietic Neoplasms Accompanied by Eosinophilia

Neoplasms in Which Eosinophils Are Likely to Be Clonal Cells
Acute eosinophilic leukemia (AEL)
Chronic eosinophilic leukemia (CEL)
Acute myeloid leukemia with inv(16) (FAB AML M4eo)
Chronic myeloid leukemia (CML, BCR::ABL1+)
Myeloid neoplasms (MLN-TK) with *PDGFR* abnormalities (WHO types)
MLN-TK with *FGFR1* abnormalities (WHO types)
Smoldering systemic mastocytosis
Aggressive systemic mastocytosis (ASM)
Mast cell leukemia (MCL)
SM-AHN (SM-CEL)
Neoplasms in Which Eosinophils May or May Not Be Part of the Malignant Clone
Other myeloproliferative neoplasms (MPN) with eosinophilia
Myelodysplastic syndromes (MDS) with eosinophilia
Other MDS/MPN overlap syndromes with eosinophilia
Indolent systemic mastocytosis
Neoplasms in Which Eosinophils Usually Are Not Part of the Malignant Clone
Hodgkin disease
B- or T-cell non-Hodgkin lymphoma
Acute lymphoblastic leukemia (ALL)
Chronic lymphocytic leukemia (CLL)
Langerhans cell histiocytosis

[a]Other MPN or MPN/MDS: neoplasms where no abnormalities in the *PDGFR* or *FGFR1* genes are detectable.

Reactive, Immunologic and Paraneoplastic Conditions Associated With Hypereosinophilia

A number of different nonhematologic malignancies may be accompanied by HE. These include, among others, solid tumors of the GI tract, adenocarcinomas of the lung, carcinomas in other internal organs, skin cancer, urogenital malignancies, and stromal cell-derived tumors. In several of these patients, the cancer cells or the cancer-related microenvironment (e.g., fibroblasts) may produce eosinophilopoietic cytokines. In many cases, PB HE but also tissue eosinophilia (tissue HE) may be recorded. In some of these cancer patients, the tumor cells are tightly surrounded and sometimes even outnumbered by the infiltrating eosinophils. So far, it remains unknown whether tissue HE and eosinophil-derived mediators contribute to tumor formation (through neoangiogenesis or tissue remodeling) or even hinder tumor formation in these patients. As mentioned earlier, lymphomas may also be accompanied by reactive/paracrine HE.

A number of different immunologic and other reactive conditions can cause reactive HE (HE$_{R}$). These include infectious diseases (e.g., helminth infections, HIV, and certain fungal infections), allergic disorders (e.g., asthma, food allergy, atopic dermatitis, and drug reactions), chronic inflammatory reactions, and autoimmune processes (see Table 74.2).[17] Treatment of the underlying disease is usually followed by resolution of HE$_{R}$, thereby confirming the etiology of HE. In most reactive conditions, HE is triggered by cytokines derived from activated immune cells, such as T cells or mast cells. In some of these patients, an underlying disease is not detectable, but clonal T lymphocytes and/or lymphocytes with an aberrant surface immunophenotype are present. In such cases, HE-related organ damage may also be seen, which leads to the diagnosis of the lymphoid variant of HES (HES$_{L}$).[15]

Specific Syndromes and Conditions Associated With Hypereosinophilia

Several specific conditions and syndromes defined by HE and organ damage may fulfill the criteria of a HES, but based on traditional views and their unique etiologies, these syndromes are still regarded as distinct entities that should be discriminated from the classical HES variants. In the future, however, most or all of these syndromes may be regarded as a special form of HES. These syndromes include, among others, episodic angioedema and eosinophilia (Gleich syndrome), CSS, eosinophilia myalgia syndrome (EMS), OS, and hyper-IgE syndrome (see Table 74.4A).

Gleich syndrome is characterized by recurrent angioedema associated with eosinophilia (HE), elevated serum cytokine (IL-5) levels, and increased (polyclonal) IgM production.[22] The episodes of angioedema and eosinophilia typically occur at monthly intervals and often resolve spontaneously without therapy. Patients with Gleich syndrome may suffer from fever and increasing body weight. The clinical course is usually benign without involvement of internal organs, thereby contrasting with the typical HES variants. In a subset of patients, the symptoms and HE persist. These patients usually respond to low-dose corticosteroids. So far, little is known about the pathogenesis of Gleich syndrome. Several lines of evidence suggest that multiple cell types are involved, including neutrophils, mast cells, eosinophils, and T lymphocytes. Whereas most of these cells are considered to be cytokine-mobilized cells, T cells are often found to be clonal in these patients. In fact, in many patients with Gleich syndrome, T-cell phenotyping reveals an abnormal phenotype of CD4^{+} lymphocytes, with decreased or absent CD3 expression (see Table 74.4A).[22] In addition, in several of these patients a clonal T-cell receptor rearrangement has been found. Therefore, Gleich syndrome has also been considered as a special (cycling) subvariant of HES$_{L}$.

CSS, also known as EGPA, is defined by a disseminated necrotizing vasculitis that is accompanied by asthma and (tissue) eosinophilia (HE).[23] EGPA is a small-vessel vasculitis characterized by the formation of extravascular granulomas and the production of antineutrophil cytoplasmic antibodies (ANCA). Both, tissue HE and the ANCAs produced in a subset of EGPA patients are considered to play an active role in disease pathogenesis. However, the exact etiology of EGPA remains unknown. More recent data suggest that EGPA may be a Th2-mediated disease. Clinically, EGPA develops in three distinct phases: the initial (early) phase is characterized by asthma and rhinosinusitis, the eosinophilic phase is defined by HE_R and HE-related organ involvement, and the late ("vasculitic") phase is defined by clinical manifestations originating from the small-vessel vasculitis (see Table 74.4A). EGPA is a systemic disease that may affect a number of different organ systems, including the lungs, skin, kidneys, nerves, and heart. Criteria for EGPA have been proposed by various expert groups. According to the American College of Rheumatology, the following criteria define EGPA: asthma, eosinophilia (>10%), neuropathy (mononeuropathy or polyneuropathy), pulmonary infiltrates, paranasal sinus abnormalities, and extravascular eosinophil infiltrates on tissue biopsies. When four out of these six criteria apply, the diagnosis EGPA can be established. Based on the considerable clinical overlap with classical HES variants, EGPA is also regarded as a special HES variant, defined by an ANCA+ vasculitis. The prognosis of patients with CSS depends on a number of clinical variables, including lung involvement, duration of disease, and response to therapy. Treatment of patients with CSS is based on the individual situation in each case and the presence or absence of prognostic factors. A combination of high-dose corticosteroids and cyclophosphamide remains a standard for treatment. More recently, antibody-based drugs, such as rituximab or mepolizumab, a humanized IL-5 antagonist monoclonal antibody, have been proposed as therapeutic alternatives and should be considered in cases resistant to cyclophosphamide.

EMS is a flu-like condition defined by recurrent episodes of myalgia and persistent eosinophilia. In many patients, neurological symptoms and skin abnormalities are found. In addition, patients may suffer from fever, weight loss, edema, and severe fatigue. The etiology of EMS remains uncertain. A clue to pathogenesis was the detection or a relationship between EMS and exposure to contaminated L-tryptophan or rapeseed oil (toxic oil syndrome). EMS is an incurable disease, but fatal cases are rare.

Eosinophilic fasciitis (EF) is a scleroderma-like syndrome with HE, polyclonal hypergammaglobulinemia, and signs of systemic inflammation. The etiology of EF remains unknown, but most authors regard EF as an immunologic hyper-reactivity disorder manifesting in the skin. Painful swelling of the skin with progressive induration and thickening of the skin and soft tissues of the limbs and trunk are typical clinical findings. Corticosteroids are usually prescribed and have been shown to be efficacious in EF patients. In a subset of patients, spontaneous improvement is found. Again, based on clinical findings and HE, it is difficult to differentiate between EF and skin involvement in HES_R. EF has been associated with the development of aplastic anemia (see Chapter 31).

OS is a rare, autosomal recessive form of severe combined immunodeficiency (SCID) associated with leukocytosis, HE, elevated IgE levels, and a high mortality rate. Recognition in early childhood is required in order to initiate life-saving therapy. OS is caused by hypomorphic missense-mutations in relevant T-cell genes, such as the recombination-activating genes *RAG1* and *RAG2* (see Table 74.4A). Unlike patients with typical SCID, patients with OS have well-populated lymphatic organs and usually suffer from diarrhea, hepatosplenomegaly, lymphadenopathy, and weight loss. In addition, severe erythroderma, increased IgE levels, and eosinophilia are found in most cases. HE and inflammation observed in these patients may result from the activity of clonally expanded T cells, which are predominantly of the Th2 type. Overall, the disease presents very similar to a graft-versus-host reaction, which is due to patients producing T cells with limited recombination ability (mutant *RAG* genes) and a specific affinity for self-antigens, making them autoreactive T lymphocytes. Other SCID-related mutations may also lead to an OS-like disease, including certain mutations in the *IL-7 receptor (IL-7R)* gene. The treatment of choice in OS is allogeneic HSCT. For patients who cannot be transplanted or need a bridging therapy prior to allogeneic HSCT, cyclosporin A (CSA) may be considered.

Hyper-IgE syndromes (HIES) are a group of rare hereditary immunodeficiency syndromes characterized by elevated IgE levels, severe recurrent infections, and HE. In many cases, skin eczema and facial anomalies are found. So far, little is known about the pathogenesis of the HIES. The disease can manifest as an autosomal dominant or autosomal recessive variant. Several different genes may be affected. In the autosomal dominant variant, *STAT3* mutations are most commonly described. Since STAT3 acts as a key transcription factor downstream of multiple cytokine receptors regulating diverse immunologic responses, impaired STAT3 function is likely to cause immunodeficiency. In the autosomal recessive HIES variants, mutations in *DOCK8* and, less commonly, in the phosphoglucomutase 3 (*PGM3*) gene, have been reported (see Table 74.4A). The natural course of HIES patients is variable, but overall the long-term prognosis is poor. Therefore, early allogeneic HSCT should be considered whenever possible.

Organ-Restricted Hypereosinophilic Syndromes

There are other clinical conditions and syndromes accompanied by HE-related organ damage that cannot be classified (diagnosed) as typical HES. A special group of such disorders are organ-restricted inflammatory conditions, such as eosinophilic colitis, eosinophilic pneumonia, or eosinophilic esophagitis (see Table 74.4B). In these patients, cytokine production and disease manifestations are typically restricted to one single-organ system, in contrast to the classical forms of HES and most of the above-described specific syndromes. The etiology of these organ-restricted HES remains largely unknown. In many instances, infectious, toxic agents or specific allergens are felt to play a pathogenetic role. In addition, genetic or epigenetic factors may contribute to disease manifestations. Depending on disease severity, suspected etiology, and presence of comorbidities, a treatment-plan is established. In many cases, corticosteroids are prescribed. In those with suspected allergy, additional drugs, such as antihistamines or leukotriene antagonists, have been recommended. The prognosis is variable and depends largely on the underlying etiology and response to treatment. Most patients respond to corticosteroids. In some patients, an underlying (initially unrecognized) systemic disease, infectious disease, or local tumor is diagnosed during follow-up. In these patients, the prognosis and treatment depend on the type and stage of the underlying disease.

TREATMENT ALGORITHM, TREATMENT OPTIONS, AND PROGNOSIS

When establishing the management plan for a patient with HE, several important questions have to be addressed. First, the final diagnosis concerning the presence or absence of HES and the presence and nature of the underlying disease, if present, have to be firmly established. Second, it is important to decide whether the patient needs symptomatic or/and interventional therapy. In some of these HE patients, a wait-and-watch strategy may be acceptable, whereas in other cases (when HES is diagnosed) specific therapy needs to be introduced quickly. Finally, the optimal treatment plan and most useful drugs need to be defined. The type of therapy varies depending on the underlying condition, targets, and the type of HES.[3,17,24]

Primary Management and Algorithm

In many cases, treatment of HES is a straightforward approach. For example, reactive HES is often managed (and resolved) quite easily by treating the underlying disease, such as a helminth infection or an autoimmune disease. In cases with idiopathic HE or HES and those with advanced or aggressive disease, however, treatment should always be performed in collaboration with a specialized center and in an interdisciplinary approach involving hematologists, immunologists, pathologists, and/or laboratory specialists, as needed.

In patients with HE_{US} and HE_F, it seems appropriate to follow the patient without treatment, provided there are no signs or symptoms of eosinophil-related organ damage despite careful medical monitoring. However, both HE_{US} and HE_F must be regarded as provisional diagnoses, and in both conditions organ damage may develop over time. In addition, a hematologic or other underlying disease may be detected during follow-up of these cases. In the reactive form of HES, it is important to define and to treat the underlying condition. Additional symptomatic therapy, often in the form of corticosteroids, may be required to control HE and eosinophil activation in these patients, especially when eosinophil counts are high or/and cells undergo rapid lysis, which may occur during treatment with cytotoxic drugs.[24]

In the past, most patients with HES received corticosteroids as front-line therapy. However, this strategy has changed with more extensive knowledge about the pathogenesis of HE and HES etiologies, and the advent of novel drugs such as PDGFR-targeting TKIs. Notably, today, front-line therapy is largely dependent on the underlying disease and the molecular targets detectable in neoplastic cells.[24] In patients in whom eosinophils display mutated forms of PDGFRs, imatinib is considered standard front-line therapy. By contrast, in patients with idiopathic HES (HES_I) and those with HES_L, corticosteroids remain standard front-line therapy. However, there are also patients in whom an initial staging and grading and/or molecular studies suggest that neither steroids nor imatinib will work. These cases include, among others, patients with an advanced myeloid neoplasm without a *PDGFR* mutation (e.g., AML-eo, MDS-eo, or SM-eo) and patients with rearranged *FGFR1* genes. In many of these cases, the primary treatment plan includes consideration of a FGFR inhibitor, for example pemigatinib or futibatinib as a bridge to HSCT.

All in all, a number of different therapeutic approaches for the treatment of HES and of the underlying (eosinophil) disorder(s) detected in these patients are available. In the following sections, these treatment approaches are briefly reviewed and discussed.

Corticosteroids

In patients with idiopathic HES (HES_I) and HES_L, corticosteroids are considered standard front-line therapy. By contrast, in patients with HES_R and HES_N, corticosteroids should only be considered as an adjunct to more specific treatment, in order to stop eosinophil activation and eosinophil recruitment (HE) as early as possible. In patients with a (suspected) infection, diabetes mellitus, an ulcerative GI tract disease, or arterial hypertension, corticosteroids should be administered with caution and with recognition of potential side effects and the related risk. In patients with HES_I and HES_L, corticosteroid therapy, usually in form of prednisone at 1 mg/kg/day (initial dose), is usually effective in reducing eosinophil counts to normal levels, with overall response rates of greater than 75% in HES_I. In contrast, most patients with HES_N do not respond to corticosteroid therapy.

The mechanisms of action by which corticosteroids suppress HE in HES_I and HES_L patients are only partly understood. Steroids act through specific corticosteroid receptors that are present in the cytoplasm of eosinophils and eosinophil precursor cells, but also in the cytoplasm of T lymphocytes and mast cells. It has also been described that steroids effectively block the production of various eosinotropic cytokines by T lymphocytes. In addition, corticosteroids effectively counteract T-cell expansion. Based on these effects, corticosteroids may act directly and indirectly to block HE in HES patients, namely by (1) inducing growth inhibition and apoptosis of eosinophils and their precursor cells, by (2) directly blocking eosinophil recruitment and migration, and by (3) inhibiting the production and release of eosinophilopoietic cytokines by T lymphocytes and other immune cells.

As mentioned earlier, long-term treatment with steroids is associated with a risk of (severe) side effects. Therefore, steroids should be tapered down (and discontinued) whenever possible, especially in cases with HES_R and HES_N. However, in many patients with HES_I, maintenance therapy with corticosteroids is required to control disease activity. In these patients, the steroid dose applied should be reduced to a minimum. In fact, even though corticosteroids are "natural" substances and very effective in reducing eosinophil counts in HES_I, chronic use of steroids is associated with the risk of serious adverse events and long-term toxicity. Once reduction of the eosinophil count to below 1.5×10^9/L and symptom control have been achieved, the corticosteroid dose should be tapered. Increases in eosinophil numbers on a prednisone dose greater than 10 mg daily and/or reappearance of symptoms or signs of organ damage are indications for the addition of other agents to the steroid regimen. A number of different drugs may be useful as steroid-sparing agents in patients with HES. These drugs include, among others, conventional cytostatic agents such as HU or cyclophosphamide, IFN-α, and IL-5 and IL-5-receptor-targeting antibodies, including mepolizumab and benralizumab, respectively.[25]

Conventional Cytoreduction and Chemotherapy

Several studies have shown that HU (0.5 to 2 g/day) is efficacious in steroid-nonresponsive patients with HES, including those with HES_I and HES_N. In patients with HES_I, HU is administered as an alternative drug or in conjunction with corticosteroids as a steroid-sparing medication. A typical starting dose is 500 to 1000 mg daily. In combination with corticosteroids, the overall response rate exceeds 50%. Eosinophil counts begin to decrease 7 to 14 days after starting HU treatment. Depending on the dose, HU may induce cytopenias. Otherwise, HU is usually well tolerated unless very high doses are administered and is therefore also used as a palliative drug in HES_N patients resistant to targeted drugs and chemotherapy. However, not all patients with HES may respond to HU. Historically, a number of cytotoxic agents have been used to treat HES refractory to steroids and HU, including vincristine, etoposide (VP-16), and chlorambucil. However, each of these agents can produce cytopenias and other side effects, and their use should be limited to select patients with HES in whom neoplastic cells develop resistance against other agents including HU. In patients with advanced, resistant CEL or AEL, but also in patients with AML-eo, intensive combination chemotherapy with or without subsequent allogeneic HSCT is usually recommended. These chemotherapy regimens are usually the same as applied in patients with refractory leukemias without HE/HES. Chemotherapy before allogeneic HSCT is often a preferable initial approach for two reasons: first, debulking may result in remission, and patients in remission are considered to have, in general, a better overall outcome after allogeneic HSCT. In addition, chemotherapy can provide some indication as to whether a patient can tolerate intensive therapy and are chemo-responsive. On the other hand, multiple cycles of chemotherapy increase the risk of infection, which may be problematic in the context of a planned allogeneic HSCT.

Interferon-Alpha

IFN-α has been used to treat HES for more than 25 years, both as monotherapy and in combination with other agents. A number of studies have shown that this type of therapy can successfully counteract HE and HES in patients in whom treatment with prednisone and HU has failed. Response rates to IFN-α vary depending on the underlying disease and dose but may be approximately 50% when used as monotherapy and 75% in combination with other agents. Usually, therapy is initiated at a dose of 1 million units three times a week and is titrated up to 4 million units three times weekly. In the responding patients, eosinophil counts decrease, and improvement in splenomegaly and hepatomegaly has been reported. Moreover, the risk of cardiac and thromboembolic complications can be reduced by treatment with IFN-α. Finally, mucosal ulcerative lesions and other skin manifestations may substantially improve. The unprocessed and the pegylated form of IFN-α appear to be equally effective and are both recommended for use in clinical practice. However, despite efficacy, the administration of IFN-α is problematic because of side effects. These side effects are often dose dependent and include fever, a flu-like syndrome, fatigue, impotence, depression, suicidal ideation, and psychosis. In addition, IFN-α therapy may lead to exacerbations of autoimmune disorders, such as autoimmune thyroiditis, psoriasis, ulcerative colitis, and others, but also to exacerbation of depression or other psychiatric diseases. Other serious adverse events observed with IFN-α include excessive suppression of blood counts, retinopathy, sarcoidosis, and left-sided heart failure. All these (potential) side effects have to be taken into account, especially when prescribing IFN-α on a long-term basis at relatively high doses. In contrast, IFN-α is nonmutagenic and is considered a drug that can be prescribed even during pregnancy. The mechanism of action of IFN-α is not well understood. Receptors for this cytokine are expressed on multipotent hematopoietic progenitor cells, eosinophil-committed precursors, and mature blood eosinophils. Therefore, in contrast to corticosteroids, IFN-α works in HES patients with diverse etiologies, including HES_L, but also in HES_N and even in HES_I. IFN-α inhibits eosinophil activation and the release of various toxic mediators from eosinophils. In addition, IFN-α may also exert an anti-inflammatory effect on other cell types that may contribute to tissue damage in HES.

Cyclosporin A

CSA, an immunosuppressant that interferes with multiple functions and growth of immunocompetent T lymphocytes, has been reported to be effective in a subset of patients with HES. The goal of CSA treatment in HES is to inhibit production of eosinophilopoietic cytokines, including IL-5, by T cells in these patients. CSA has been used as a single agent or in conjunction with low-dose corticosteroids. In those with steroid-sensitive disease, CSA may act as a steroid-sparing agent. However, good responses may only be seen in distinct variants of HES, namely those HES variants where T-cell activation is a causative etiology. Another important point is that efficacy has so far only been described for CSA in short-term–treated HES patients (10 months), whereas long-term efficacy has not been determined so far. In each case, the side effects and immunosuppressive effects of CSA have to be taken into account. In patients with HES_N, CSA should not be administered.

Targeted Treatment Approaches Using Tyrosine Kinase Inhibitors

Several different oncogenic kinases have been detected in primary eosinophilic disorders (MLN-TK, CEL, and MPN-eo) and serve as targets of therapy.[13] The most relevant and most frequent target kinase detectable in these patients is *F/P*. This fusion gene product is a target of imatinib and also sensitive to other TKIs, such as nilotinib, dasatinib, midostaurin, or ponatinib. A number of other oncoproteins may also serve as targets of imatinib and are detectable in primary eosinophil disorders. Several of these fusion genes involve *PDGFRA* or *PDGFRB*, whereas FGFR1 mutants are resistant against imatinib. The hematologic benefit of imatinib in *F/P*-positive neoplasms and *PDGFRB*-rearranged neoplasms has been confirmed in several clinical trials.[26,27] Therefore imatinib is regarded as standard first-line therapy in these patients. Given the poor prognosis of patients with overt organ damage (HES_N), patients with an *F/P*+ neoplasm or another mutation involving *PDGFRA* or *PDGFRB* genes should be treated with imatinib, even in the absence of end-organ damage, in order to prevent any HES occurrence. Although the optimal dosing strategy for imatinib has not been fully defined, a number of studies have shown that a daily dose of 100 mg appears to be sufficient to induce complete hematologic and molecular remission in most patients.[26] Imatinib is several hundred–fold more potent against *FIP1L1::PDGFRA* compared to BCR-ABL1 as a target. Moreover, 100 mg imatinib/day appears to be a safe approach in all patients, including those who suffer from cardiac involvement. Therefore, 100 mg/day is regarded a standard dose of initial therapy with imatinib in *F/P*+ patients. However, in a few patients with *PDGFRA*- or *PDGFRB*-rearranged neoplasms, higher doses of imatinib (400 mg daily) are required to induce a durable remission. In those who enter a hematologic and molecular remission, imatinib is usually maintained, as discontinuation is often followed by a relapse.[28] However, it remains unknown whether all patients need to continue on their initial dose on a life-long basis. In fact, many of these patients do not relapse when lowering the dose of imatinib or even when imatinib is discontinued. In other patients, however, resistance to imatinib may occur. In relapsing patients, *F/P* point mutations associated with decreased (or loss of) drug-binding capacity may be detected. For these patients, novel TKIs or chemotherapy may be considered. The most commonly detected mutant, T674I, leads to replacement of threonine by isoleucine at residue 674 in the FIP1L1::PDGFRA kinase domain, resulting in resistance to imatinib. This T674I exchange is analogous to the *BCR::ABL1* T315I mutation, which is a pan-resistant mutation to several TKIs except for ponatinib. Although in vitro sensitivity has been demonstrated to a number of different TKIs with this mutation (e.g., midostaurin, nilotinib, sorafenib, and ponatinib), clinical responses are often disappointing. Other secondary mutations in *F/P*+ disease, such as D842V, are very rare. However, once these secondary mutations occur during treatment with multiple TKIs, they usually exhibit pan-resistance. In fact, durable responses to TKIs with either the T674I or D842V mutation are not generally observed, and especially the *F/P* D842V mutant is resistant to almost all available TKIs. It has also been described that ponatinib can kill neoplastic eosinophils exhibiting all types of *F/P* mutations in vitro at clinically achievable drug concentrations. Whether this also holds true in vivo in patients with TKI-resistant CEL or acute leukemias exhibiting this *F/P* mutant, presently remains unknown. Avapritinib, which is now approved for D842V-mutated gastrointestinal stromal tumors, may have activity in *FIP1L1::PDGFRA*-positive disease with the D842V mutant, but this has not yet been reported at the time of this writing. Another approach in patients with TKI-resistant eosinophil neoplasms is to apply cytoreductive agents (IFN-α, HU) or experimental drugs. In patients who transform to an acute leukemia, combination chemotherapy and allogeneic HSCT are usually recommended.

A number of different markers have been proposed for the monitoring of treatment responses in patients with *F/P*+ CEL. Close hematologic follow-up is recommended for the first weeks of therapy, where a rapid decline in eosinophils (and leukocytes) is usually observed and is regarded a good prognostic sign. After a few months, the BM should be examined in order to document and confirm the hematologic response. A complete remission is obtained in most patients, even if the initial BM revealed marked involvement at diagnosis, including fibrosis and/or increased blast cells. In patients with a complete hematologic remission, molecular monitoring and repeated PCR and FISH analysis is recommended in order to define the molecular response. Quantitative measurement of the *F/P* mRNA burden by reverse-transcriptase-PCR is available in many centers and can be employed to define the depth of the remission. In those with an initially elevated serum tryptase, serial determinations of tryptase are also useful to document the response to imatinib or other TKIs. Finally, in those with end-organ damage, including cardiac disease, reinvestigation of all involved organ systems is recommended to demonstrate potential reversion of end-organ damage. In high-risk patients (e.g., cardiac history), echocardiography and troponin as well as B-type natriuretic peptide levels before initiating therapy may be recommended to gauge the potential risk.

Although imatinib and other TKI therapies in HESN patients is generally well tolerated, all these agents can produce severe side effects. Even imatinib may produce severe side effects, especially when applied to HES patients with cardiopathy at 400 mg daily. In fact, in a few cases severe left ventricular dysfunction (presumably due to rapid cytoreduction of eosinophil infiltration of the endomyocardium) has been reported soon after initiation of imatinib therapy; therefore, in patients with known or suspected cardiac involvement, it is recommended that corticosteroids be initiated for the first 7 to 10 days of imatinib therapy and close monitoring is recommended during this period. The second- and third-generation TKIs used to treat CML and CEL may also produce severe side effects, and many of them may affect the cardiovascular system or metabolic parameters, which is relevant clinically in the context of HES.

Targeted Antibodies

A number of targeted antibodies and antibody–toxin conjugates have been considered for patients with HE-related disorders and HES.[25,29] These antibodies are directed either against (neoplastic) eosinophils and their precursor cells or against eosinotropic cytokines, such as IL-5. Anti-eosinophil antibodies are considered useful in neoplastic states and should ideally be directed against both eosinophils and their precursor cells, or even neoplastic stem cells. One such antibody is alemtuzumab. This humanized antibody is directed against CD52 (= Campath-1), a surface receptor expressed on neoplastic stem cells in various leukemias as well as on eosinophils and their precursor cells. Alemtuzumab therapy in patients with drug-resistant eosinophil disorders has been reported in a limited number of studies. In about 80% to 90% of the patients the drug induced remission. However, in over 80% of these patients, relapses occurred after cessation of therapy. In addition, alemtuzumab produced substantial side effects, including severe hematological toxicity with subsequent opportunistic infections. Several other antibodies directed against cell surface receptors expressed by eosinophils are currently in preclinical development. The epidermal growth factor-like module-containing, mucin-like hormone receptor 1 (EMR1) is expressed specifically on human blood eosinophils and may serve as a potential target of therapy. A novel, humanized afucosylated anti-EMR1 IgG1 antibody has recently been shown to augment NK cell-mediated killing of eosinophil granulocytes. Benralizumab is an antibody directed against the IL-5 receptor on eosinophils and their precursor cells. So far, benralizumab has been tested in normal subjects, patients with asthma, and patients with HES.[29,30] BM studies have shown that this antibody induces a remarkable depletion of eosinophils and their precursor cells. It is noteworthy that the IL-5 receptor is also expressed on basophils, albeit at lower levels. The trial showed that benralizumab therapy was effective in a small group of patients of reducing blood and tissue eosinophilia with few or no toxic effects in patients with severe, treatment-refractory HES, despite having markedly higher eosinophil levels. The eosinophil-lowering effect of benralizumab was sustained in the majority of patients allowing the tapering of other therapies that had substantial long-term toxic effects. A larger, well-controlled, multicenter trial of benralizumab is ongoing to confirm these results and further explore the role of clinical disease subtype and other factors in the treatment response in patients with HES. Another interesting target receptor is Siglec-8. This antigen is expressed on eosinophils and mast cells, but not on neoplastic stem cells. Remarkably, Siglec-8 crosslinking induces eosinophil apoptosis and inhibits IgE-mediated mast cell activation, thereby providing a common mechanism to limit inflammation caused by the coexistence and functional interactions of these cells.[6] Whether this concept is clinically effective, remains at present unknown. Since Siglec-8 is not expressed on immature eosinophilic progenitor cells or neoplastic stem cells, the drug may not be useful in eosinophil malignancies. A humanized non-fucosylated IgG1 monoclonal antibody, AK002, has entered clinical trials for the treatment of various eosinophilic diseases including eosinophilic gastritis and/or gastroenteritis, antihistamine-resistant chronic urticaria, and severe allergic conjunctivitis. AK002 was found to reduced GI eosinophils and symptoms in a phase 2 study of symptomatic eosinophilic gastritis and/or duodenitis.

Siglec-3 (CD33), another established drug target, is displayed by normal and neoplastic eosinophils and even by neoplastic stem cells. Gemtuzumab ozogamicin (GO) is a humanized CD33 antibody conjugated with calicheamicin. The drug is highly effective in targeting myeloid cells and their progenitors in AML. The drug can also produce prolonged cytopenia, especially when used with combination chemotherapy. However, when used at limited doses and at reasonable time intervals, the toxicity of such antibodies may be acceptable.

Another approach, for patients with reactive HE and HES (HES_R) as well as HES_L, is to target eosinotropic cytokines using specific antibodies, where overproduction of such cytokines is known to play a pathogenetic role. These agents include antibodies directed against IL-5, against eotaxin, or other cytokine agonists. Mepolizumab is a fully humanized IgG1 antibody that binds IL-5 and prevents its binding to the IL-5 receptor alpha chain.[29] Mepolizumab was tested against placebo in a randomized, multicenter, double-blind, placebo-controlled, phase III trial of mepolizumab. Patients were randomized (1:1) to subcutaneous mepolizumab (300 mg) or placebo every 4 weeks for 32 weeks, plus existing HES therapy. The primary outcome was the proportion of patients with 1 or more flares (worsening of HES-related symptoms necessitating therapy escalation or ≥2 courses of blinded rescue oral corticosteroids). The proportion of patients experiencing one or more flares/withdrawing from the study was 50% lower with mepolizumab versus placebo.[25] Adverse events were tolerable and similar in the treated and in the placebo groups. Based on these data, mepolizumab was approved by the FDA in 2020 for the treatment of patients with HES, and follows prior approvals for severe eosinophilic asthma and EGPA. Reslizumab is a humanized IgG4 anti IL-5 antibody that is currently being tested in clinical trials for eosinophilic esophagitis and in pediatric patients for eosinophilic asthma, but it has not been studied in the context of HES.[29] Initial results suggest that the drug is effective in reducing eosinophil counts and clinical symptoms. Bertilimumab is a human anti-eotaxin-1 antibody that is currently being tested in a phase II clinical trial for ulcerative colitis but has not been tested yet in HES patients. Together, more controlled clinical trials in HES patients are needed to learn which antibodies directed against eosinophilic receptors and eosinotropic cytokines are most effective in patients with primary or reactive eosinophil disorders and HES.

Leukapheresis

Leukapheresis has no defined role in the management of HES. However, leukapheresis may be useful in emergency situations for patients with excessively high eosinophil counts. Since cell counts rebound rapidly to pretreatment levels, such a maneuver should always be combined with cytoreductive therapy in order to keep eosinophil counts under control.

Anticoagulation and Antiplatelet Agents

Thromboembolic complications may be life-threatening in HES patients. Therefore, prophylactic anticoagulation may be considered in patients with HES, especially in those in whom the risk for thromboembolic complications is high, such as in patients with a *F/P*+ disease, cardiac involvement, or neurologic symptoms. In patients with overt HES and associated thromboembolic events, anticoagulation is a standard approach. Commonly used agents are warfarin, antiplatelet agents, direct acting oral anticoagulants and heparin. The efficacy of these drugs has not been formally established in HES, and some of the patients may continue to have thrombotic events, despite adequate anticoagulation. Therefore, it is always important to treat the underlying disease if possible, in order to reduce the thromboembolic risk.

Splenectomy

Splenectomy is usually not required in patients with MPN-eo, AEL, or CEL. However, in rare cases, splenomegaly has been performed to correct hypersplenism-related cytopenias, or to avoid splenic infarction and pain induced by capsular distention.

Allogeneic Hematopoietic Stem Cell Transplantation

Although the experience with allogeneic HSCT in patients with advanced BM neoplasms accompanied by HE (with or without HES) is quite limited, allogeneic HSCT should be considered in certain groups of patients, especially those who (1) are young and fit, (2) have a suitable transplant donor, and (3) have a progressive and treatment-resistant form of an underlying myeloid or lymphoid neoplasm. More or less definitive indications in this regard include *FGFR1*-rearranged neoplasms, drug-resistant forms of AEL or CEL, chemotherapy-resistant peripheral T-cell lymphomas accompanied by HE/HES, and treatment-resistant (progressive) cases of MPN-eo, AML-eo, or MDS-eo. When the burden of neoplastic cells is high, debulking therapy should be introduced prior to conditioning and HSCT. Such debulking may be performed with combination chemotherapy or with experimental drugs. Several but not all transplanted patients may enter a complete remission. Transplant-related mortality rates may not be higher compared to age-matched patients with other advanced hematopoietic neoplasms. As in other BM neoplasms, age, comorbidities, and the disease status are major risk factors concerning survival and transplant-related mortality. In this regard, it should be noted that the presence of HES-related organ damage, such as overt cardiomyopathy or thromboembolism, but also neuropathies or GI disease, may count as relevant comorbidities, and if severe in nature, may represent a contraindication to allogeneic HSCT. In those who are successfully transplanted, the clinical course may be complicated by graft-versus-host disease requiring treatment with corticosteroids, cyclosporin-A, or/and other immunosuppressive drugs. Little is known about long-term outcomes after allogeneic HSCT. In smaller case series and single cases reports, long-term survivors have been described. However, relapses have also been reported in most groups of patients.

Cardiac Surgery

In a subset of patients with HES, surgical intervention of cardiac lesions is required. Interestingly, such intervention does not appear to carry a major risk for disease recurrence at the operative sites. Indications for surgery include a significant compromise of valvular function and the presence of a clinically significant thrombotic mass. Cardiac surgery has the capacity to provide a substantial clinical and quality-of-life benefit in these patients. In fact, successful mitral valve and/or tricuspid valve repair or replacements have been reported in HES patients in several studies. For mitral valve replacements, mechanical valves have proven problematic because of recurrent thrombosis despite adequate anticoagulation, suggesting the use of porcine valves whenever possible. HES patients who have received valve replacements have generally experienced long-term improvement in cardiac function, provided the underlying disease and the related HE can be kept under control.

SUMMARY AND FUTURE PERSPECTIVES

The diagnosis, classification, and management of patients with persistent HE remain a challenge in clinical practice, especially when no underlying disease is identified and/or HE-related organ damage (HES) develops. Because of heterogeneity and complexity of the disease, each case needs to be investigated and managed using the full battery of diagnostic markers and assays, and according to contemporary diagnostic and therapeutic algorithms.[3,14] Depending on the overall situation, initial investigations include BM studies (histology, cytology, and cytogenetics with FISH), molecular analyses, immunologic parameters, and a complete staging of all potentially involved end-organ systems. In benign disease variants, the course can sometimes be monitored without specific treatment. However, in patients with (1) advanced hematopoietic neoplasms, (2) overt HE-related end-organ damage (HES), (3) an active underlying (systemic) immunologic, infectious, or allergic disease, (4) evidence of a specific clinical syndrome with systemic organ involvement, or (5) organ-restricted marked inflammation associated with eosinophilia, such as eosinophilic colitis or eosinophilic pneumonia, specific treatment needs to be initiated. In reactive conditions, symptomatic treatment and corticosteroids are usually administered. In addition, it is of utmost importance to treat and eradicate (or control) the underlying disease, such as an NHL, helminth infection or IgE-dependent allergy, in these patients. Such treatment is often followed by complete resolution of reactive HE and of the related HES. In treatment-resistant patients in whom reactive eosinophilia is likely to be triggered by eosinophilotropic cytokines such as IL-5, anti-cytokine therapy, such as mepolizumab, may be considered.[29,30] This drug has shown promising results in patients with steroid-resistant reactive HES and other HE-related conditions, such as eosinophilic esophagitis. In advanced hematopoietic neoplasms, treatment with targeted drugs or less specific cytoreductive agents is recommended.[31,32] In *F/P*+ patients and those with related *PDGFR* fusion genes, imatinib is an undisputable standard of therapy. For patients with imatinib-resistant *F/P*+ CEL or MPN-eo, MPN-eo without a *PDGFR* mutant, or HE-related malignancies expressing *FGFR1* or *JAK2* fusion genes, novel TKIs are available.[31,32] In patients in whom secondary mutations in *F/P* are detectable, novel PDGFR-targeting TKIs such as ponatinib or avapritinib may work. In cases with *FGFR1*-rearranged neoplasms, novel FGFR inhibitors such as pemigatinib may overcome resistance, and in patients with *JAK2*-mutated MPN-eo, ruxolitinib may elicit clinically meaningful responses. In rapidly progressive and/or drug-resistant cases, high-dose chemotherapy and allogeneic HSCT need to be considered. In patients who are TKI resistant and not eligible for allogeneic HSCT, HU, other cytostatic agents, or IFN-α serve as palliative drugs. Current research aims at exploring the evolution of HES and at defining mechanisms regulating the development of HE-mediated end-organ damage, which should lead to more selective and improved therapies in the future. Clinically relevant targets for these efforts are likely to include (1) neoplastic stem cells producing eosinophil neoplasms such as CEL or MPN-eo, (2) molecular targets created specifically by neoplastic cells, such as mutant forms of *PDGFRs* or *FGFRs*, (3) eosinophilotropic cytokines and their receptors, (4) underlying T-cell clones triggering eosinophil expansion and/or activation through production of eosinopoietic cytokines, (5) adhesion receptors and other molecules mediating eosinophil homing and redistribution, such as VLA-4, and (6) signaling molecules responsible for cytokine-dependent or -independent eosinophil proliferation, migration, adhesion, or/and activation. Another aim for the future is to better understand cellular interactions and related molecular mechanisms underlying HE-induced organ damage (HES) in various organ systems. There is hope that an improved knowledge of mechanisms regulating end-organ damage will lead to the development of new treatment concepts and better therapies for patients with HES.

CHAPTER 75

MAST CELLS AND MASTOCYTOSIS

Jason Gotlib, Hans-Peter Horny, and Peter Valent

Paul Ehrlich used his 1878 doctoral thesis to characterize a new cell type—the mast cell (MC)—based on its reactivity to aniline dyes and the metachromatic appearance of its cytoplasmic granules.[1] He referred to MCs as *Mastzellen* and he speculated that their intracellular granules contained phagocytosed materials or nutrients. Ehrlich also described a close relationship in tissues between MCs and blood vessels, nerves, gland excretory ducts, as well as their proximity within the environment of tumors and chronic inflammation. In 1894, the pathobiologic association of MCs with lesions of urticaria pigmentosa was reported,[2] and from the 1930s forward, basic incremental discoveries about normal MC functions were made. Their capacity to undergo degranulation in response to various stimuli, their source of histamine and heparin, and their important role in anaphylaxis was examined.[3–10]

Perturbations of MC growth and function may lead to mastocytosis, a condition defined by pathologic expansion and accumulation of MCs in diverse tissues such as the skin, bone marrow (BM), spleen, liver, lymph nodes, and gastrointestinal (GI) tract. In 1949, the first case report of systemic mastocytosis (SM) was published. Later, between 1950 and 1980, several different subtypes of SM were described, including a leukemic variant termed *mast cell leukemia* (MCL). The first classification of mastocytosis was created by the Kiel group of pathologists, and in 1991 the first consensus classification was published. Criteria for SM and other variants of the disease were established between 1990 and 2000. In 2000, these criteria were discussed by a consensus group and were employed to establish a robust consensus classification of mastocytosis,[11] that was adopted by the World Health Organization (WHO) in 2001 and also in 2008.[12] In consecutive years, the consensus group published treatment response criteria and established a widely accepted update of the classification of mastocytosis in 2007.[13] In this updated classification, the smoldering state is defined as a separate category of SM which was confirmed by the WHO in 2016. In 2002, the European Competence Network on Mastocytosis (ECNM) was founded. Since then, the ECNM has facilitated basic science and translational research dealing with mastocytosis and related MC disorders. In 2019, the American Initiative in Mast Cell Diseases (AIM) was formed with similar and complementary goals to the ECNM, including fostering collaborative translational and clinical research projects in MC disorders. This chapter provides an overview of normal MC physiology and highlights contemporary issues related to the classification, diagnosis, and treatment of SM.

ORIGIN AND DEVELOPMENT OF MAST CELLS

The marrow origin of MCs was first demonstrated by engrafting BM cells into irradiated mice. Human MCs can be generated from CD34$^+$ hematopoietic stem and progenitor cells in response to stimulation with stem cell factor (SCF). In vitro MC differentiation models showed that circulating MC progenitors express CD13, CD34, and KIT, but lack CD14 and CD17.[14,15] MC progenitors are released from the BM into the circulation in a primitive state and undergo terminal maturation and differentiation after their migration to tissues. Although shared histomorphologic and biologic features of MCs and basophils include cytoplasmic basophilic granules, expression of high-affinity immunoglobulin (Ig)E receptors (FcεRI), and release of histamine upon stimulation, basophils exhibit several distinctive characteristics. Basophils circulate as mature cells, which are incapable of proliferation, and subsequently undergo apoptosis after their recruitment and activation in the tissues. Differential expression of the transcription factor CCAAT-enhancer-binding protein (CEBP)α may be a primary determinant of whether development is skewed toward basophil progenitors (CEBPα present) or MC progenitors (CEBPα absent). Although eosinophils and basophils have been found to share a common bipotential progenitor in humans, definitive data for a similar progenitor giving rise to both basophils and MCs are lacking. Rather, based on in vitro colony assays, MCs are directly derived from multilineage and lineage-restricted progenitors, but not from such a bi-potent precursor cell.[6] In line with this observation, evidence against a bilineage basophil/MC progenitor also came from tracking lineage involvement of *KIT* D816V in patients with SM, where *KIT* D816V was only found in basophils in a small subset of patients, namely those with multilineage involvement of the mutation. In addition, when highly enriched by cell sorting, neither mature blood basophils nor mature blood monocytes give rise to MCs in vitro.[16]

Collectively, these data suggest that normal human MCs are derived from CD34$^+$ stem and progenitor cells but not from a more mature myeloid cell and that MCs form a unique cell lineage in the hematopoietic cell system. Correspondingly, in 2019, Eisenwort and colleagues described that the leukemia-initiating stem cell in MCL resides within the CD34$^+$/CD38$^-$ fraction, but not in CD34$^+$/CD38$^+$ progenitors or bulk KIT$^+$/CD34$^-$ MCs.[17]

KIT and Stem Cell Factor (KIT Ligand)

KIT

Kit is the cellular homolog of the *v-Kit* oncogene of the Hardy-Zuckerman 4 feline sarcoma virus. The human *KIT* gene on chromosome 4q11–12 was found to be allelic to the white spotting locus (*W*) in mice, in which over 30 mutations have been identified. The common theme of mutant alleles at the *W* locus is decreased kit kinase activity either through missense mutations that generate kinase-defective kit (e.g., W^{42} [*kit* D790N]; W^{37} [*kit* E582K]; W^{v} [*kit* T660M]; and W^{41} [*kit* V831M]) or decreased expression of kit on the cell surface (e.g., the *W* allele, caused by a 78-amino acid deletion that involves the transmembrane (TM) region of the kit protein).

Double mutants at the murine *W* locus not only result in markedly decreased MC numbers, but also in pleiotropic phenotypes, including white coat color/spotting, sterility, and anemia, that respectively relate to the failure of melanocytes, germ cells, and hematopoietic progenitors to migrate and/or proliferate effectively during development (see Chapter 9). Heterozygosity or homozygosity for the different alleles at the *W* locus results in variable phenotypic effects on hematopoiesis, pigmentation, and fertility. Mutations at the *W* locus can also result in abnormalities of the interstitial pacemaker cells of Cajal, leading to functional gut abnormalities, such as megacolon. Intriguingly, some of these clinical correlates can also be seen in patients undergoing long-term treatment with a strong KIT inhibitor, like imatinib: these individuals can develop MC deficiency, depigmented skin areas, cytopenias, and fertility problems.

KIT is a member of the type III receptor tyrosine kinases (TKs) that also include platelet-derived growth factor receptor (PDGFR)-α and -β, FMS-like tyrosine kinase-3 (FLT3), vascular endothelial growth factor receptor 2 (VEGFR2), and the receptor for macrophage colony-stimulating factor (FMS).[18,19] These TKs share common structural motifs including an extracellular domain containing five Ig-like motifs that bind their specific ligands, a short TM domain that anchors KIT to the cell membrane, a cytoplasmic TK domain that is split by an insert sequence into ATP-binding and phosphotransferase regions, and a juxtamembrane (JM) domain that lies between the TM and TK domains. KIT is expressed on hematopoietic stem/progenitor cells and is also essential for gametogenesis and melanogenesis. KIT expression is lost when hematopoietic cells undergo differentiation. However, MCs do retain persistent and high-level expression of KIT (CD117). This can be exploited for the purposes of MC identification by immunohistochemistry and/or flow immunophenotyping (in conjunction with other surface and cytoplasmic markers).

The two major splice variants of KIT differ by the presence or absence of four amino acids (GNNK) at the extracellular JM region. In NIH3T3 cells, the GNNK$^-$ isoform induced loss of contact inhibition, anchorage-independent growth, and tumorigenicity in mice, whereas the GNNK$^+$ isoform did not exhibit most of these characteristics. Also, despite similar binding of SCF to KIT, the GNNK$^-$ isoform displayed more rapid and extensive tyrosine autophosphorylation and faster internalization. Preferential expression of the GNNK isoform has been noted in small cohorts of patients with SM and germ cell tumors, but larger series are needed to determine the relevance of these KIT isoforms to disease pathogenesis.

Stem Cell Factor

SCF (KIT ligand) was identified by three groups in 1990 as the principal growth and differentiation factor for human MCs.[20–22] In fact, SCF was found to induce MC differentiation from CD34$^+$ cells or blood/BM mononuclear cells.[23,24] SCF is produced by fibroblasts and endothelial cells, and promotes the proliferation, differentiation, survival, and migration of hematopoietic progenitors, melanocytes, MCs, and germ cells.

Loss-of-function mutations at the *Sl* (steel) locus on chromosome 10 in mice were found to phenocopy mutations at the *W* locus (see Chapter 9). Ultimately, the gene product of the *Sl* locus was found to be the ligand for kit, SCF. In the case of mutations affecting the *W* (kit) locus, transplantation of BM cells from congenic +/+ mice into W/W^v mice corrected MC deficiency and anemia, consistent with an intrinsic progenitor/stem cell defect. In contrast, skin and BM engraftment experiments demonstrated that mutations at the *Sl* locus were cell extrinsic (e.g., microenvironmental) in nature. When skin from either W/W^v or Sl/Sl^d mice was transplanted onto the backs of congenic +/+ mice, MCs were capable of engrafting the skin from W/W^v mice but not the skin from Sl/Sl^d mice. In addition, hematologic abnormalities in Sl/Sl^d mice failed to correct with transplantation of BM cells from congenic +/+ animals. These experiments formally established that SCF is a physiologically relevant ligand of kit and that development is critically dependent on this ligand-receptor interaction. Therefore, SCF has also been termed *MC growth factor*.

Alternative splicing results in two isoforms of membrane-bound SCF with different susceptibility to proteolytic cleavage: a longer isoform that retains exon 6 and contains a cleavage site that results in soluble SCF, and a shorter isoform lacking the cleavage site, which remains membrane-bound and serves as a stem cell homing receptor in the BM niche. Both the membrane-bound and soluble form of SCF (which exists in a homodimeric confirmation) are capable of binding to and inducing homodimerization of KIT, which, in turn, leads to autophosphorylation of tyrosine residues located in intracellular portions of the molecule. A cascade of signaling events ensues via downstream effector molecules, including Src kinases, c-Jun N-terminal kinase (Jnk), mitogen-activated protein (MAP) kinases, and the Janus-activated kinase (JAK)-signal transducer and activator of transcription and phosphatidylinositol 3-kinase (PI3K)/AKT pathways.[25–27] In addition to promoting MC differentiation and survival, SCF can regulate MC adhesion to extracellular matrix proteins as well as mediator release via IgE-dependent and IgE-independent mechanisms. Likewise, when applied at relatively high concentrations for 90 minutes, SCF is capable of directly inducing mediator secretion from human MCs. Whereas in mice several different cytokines are involved in the regulation of growth and activation of MCs, SCF seems to be a rather specific cytokine for human MCs. Other studies have shown that certain cytokines or hormonal factors exert inhibitory effects on MCs (e.g., interferon [IFN]-γ), and some cytokine pairs counterbalance each other's effects (e.g., T-helper 2 [Th2] cytokine interleukin [IL]-4 vs. regulatory T-cell cytokine TGF-β1) on MC homeostasis. Expression of the death receptor tumor necrosis factor–related apoptosis-inducing ligand and inhibitor receptors CD300a and Siglec-8 may also contribute to downregulation of MC activation, survival, and IgE-mediated responses.[28,29]

MAST CELL ACTIVATION AND FUNCTION

MCs commonly reside at the interface between the host and environment, usually in the skin, or in the mucosa lining the lungs or GI tract. Migration and homing of MCs to various sites is regulated by the interaction between surface expression of numerous types of chemokine receptors (e.g., CXC chemokine receptor 2) and integrins (e.g., α4β7, α4β1) on MCs to tissue-specific endothelial binding sites such as mucosal vascular address in cell adhesion molecule-1 (MAdCAM-1) and vascular cell adhesion molecule-1 (VCAM-1). In addition to playing a primary role in mediating allergic responses and inflammation, MCs act as one arm of the adaptive immune system by playing a role in host defense against pathogens such as bacteria, fungi, and viruses.

MCs serve as a rich source of a variety of biologically active molecules (Table 75.1).[10] These include preformed mediators such as vasoactive amines (histamine), anionic proteoglycans (heparin, chondroitin sulfate), and proteases (tryptase, chymase, and carboxypeptidase). Activated MCs also contribute to de novo synthesis of lipid-derived mediators that constitute the slow-reacting substance of anaphylaxis (SRS-A). These mediators include lipoxygenase-derived metabolites of arachidonic acid—the cysteinyl leukotrienes LTC4, LTD4, and LTE4, and cyclooxygenase-derived prostaglandin (PG)D2. These substances are involved in mediating vasodilation and vasopermeability, smooth muscle constriction, mucus secretion, and other proinflammatory sequelae. IgE- and non-IgE–dependent mechanisms (e.g., IgG, complement [C3a, C5a], neuropeptides, narcotics, physical stimuli, and activation of Toll-like receptors by bacterial products) can induce MCs to release a variety of cytokines (e.g., TNF-α, macrophage inflammatory protein [MIP]-1α and -1β, monocyte chemoattractant protein [MCP]-1, IFN-α, -β, and -γ, and various ILs) and growth factors (see Table 75.1) that are implicated in the aforementioned physiologic roles of inflammation, allergic responses, and host defense.[10,30] MCs mediate early-phase (e.g., anaphylaxis, acute asthma) and late-phase allergic responses, as well as non–type I hypersensitivity reactions through their proinflammatory mediators. Furthermore, MCs mediate upregulation of Th2 responses and allergen-specific IgE biosynthesis, which contribute to host defense against parasitic infections. MCs have also been implicated in the pathogenesis of various nonallergic conditions such as infectious or autoimmune diseases (e.g., multiple sclerosis, psoriasis, rheumatoid arthritis, inflammatory bowel disease), and also in repair after tissue injury, such as wound healing, thrombolysis, or tissue remodeling.

Coupling of MCs and eosinophils often occurs in the same tissue niches in allergic/inflammatory and neoplastic disorders such as eosinophilic esophagitis, chronic gastritis, GI neoplasms, parasitic infections, and inflammatory bowel disease. MCs can initiate the allergic inflammatory cascade, resulting in recruitment of eosinophils

TABLE 75.1 Human Mast Cell Cell–Derived Mediators

Class	Mediators	Physiologic Effects
Preformed mediators	Histamine, serotonin, heparin, neutral proteases (tryptase and chymase, carboxypeptidase, cathepsin G), major basic protein, acid hydrolases, peroxidase, phospholipases	Vasodilation, vasoconstriction, angiogenesis, mitogenesis, pain, protein processing/degradation, lipid/proteoglycan hydrolysis, arachidonic acid generation, tissue damage and repair, inflammation
Lipid mediators	LTB4, LTC4, PGE2, PGD2, PAF	Leukocyte chemotaxis, vasoconstriction, bronchoconstriction, platelet activation, vasodilation
Cytokines	TNF-α, TGF-β, IFN-α, IFN-β, IL-1α, IL-1β, IL-5, IL-6, IL-13 IL-16, IL-18	Inflammation, leukocyte migration/proliferation
Chemokines	IL-8 (CXCL8), I-309 (CCL-1), MCP-1 (CCL2), MIP-1αS (CCL3), MIP1β (CCL4), MCP-3 (CCL7), RANTES (CCL5), eotaxin (CCL11), MCAF (MCP-1)	Chemoattraction and tissue infiltration of leukocytes
Growth factors	SCF, M-CSF, GM-CSF, bFGF, VEGF, NGF, PDGF	Growth of various cell types, vasodilation, neovascularization, angiogenesis

The mediators in the table are examples only. In addition, many mediators are identified in mouse mast cells, human mast cell lines, or primary cultures of human mast cells and may not be produced in vivo.
IFN, Interferon; *IL*, Interleukin; *MCP*, monocyte chemoattractant protein; *MIP*, macrophage inflammatory protein; *SCF*, stem cell factor.
From Metcalfe DD. Mast cells and mastocytosis. *Blood*. 2008;112:946.

during the later phases of an allergen encounter. Both MCs and eosinophils express CCR3 and respond to eotaxins and RANTES (CCL5), leading to recruitment of both cell types into inflamed tissue (see Chapters 14 and 15).[31] Moreover, MC-derived heparin can bind and stabilize eotaxins. In addition, MCs and eosinophils can interact with each other through soluble mediators or via direct cell-to-cell contact. At least in the murine system, MCs can also be induced to produce IL-3 and IL-5, which can potentiate eosinophil recruitment in tissues.[32] The two principal MC-derived proteases exert dual actions on eosinophils. For example, MC-derived chymase suppresses eosinophil apoptosis and induces release of IL-6, CXCL8, CCL2, and CXCL1 from eosinophils. In contrast, β-tryptase can cleave eotaxin and RANTES, and can limit eosinophil chemotaxis. Eosinophils in turn produce SCF, which can attract more tissue MCs and protect them from apoptosis.

IgE-mediated hypersensitivity reactions (e.g., allergic rhinitis or asthma, anaphylaxis) are mediated by binding of allergen-specific IgE to the high-affinity FcεRI receptor, which is constitutively expressed at a high level on MCs. Engagement of FcεRI leads to its inclusion in lipid rafts, and phosphorylation of its β- and γ-chain immunoreceptor tyrosine-based activation motifs (ITAMs) by Lyn kinase and subsequent activation of Syk kinase through its binding to the ITAMs.[27] These proximal signaling events also activate Fyn kinase, which is important for phosphorylation of the adaptor protein Gab2 and activation of the PI3K pathway. Lyn kinase also regulates phosphorylation of the protein scaffolds LAT and NTAL, which coordinate multiple signaling pathways including Ras/MAP kinase, TEC family kinases, and PLCγ activation.[33] PLCγ, in turn, is a critical mediator of MC cytokine production and degranulation.

Experimental data indicate that the functions of KIT and FcεRI in MCs are interdependent. It has been observed that SCF enhances FcεRI-mediated MC degranulation, and that phosphorylation of the membrane adaptor molecule NTAL is a crucial link between the signaling cascades following KIT activation and FcεRI aggregation. In addition, BTK is a mediator of FcεRI-mediated MC degranulation and plays a critical role in the amplification of FcεRI activation by KIT.[34]

TOOLS TO STUDY HUMAN MAST CELLS

The challenges of studying MCs relate to heterogeneity in their morphology and function between different species, and also within different tissues of the same organism. Although several techniques, including flow cytometry-based cell sorting, exist for ex vivo isolation of BM MCs, yields are typically low, reflecting the low numbers of MCs in the BM and the difficulties in isolating them from other tissues, such as the lung. Ex vivo generation of human cord blood–derived or peripheral blood–derived MCs from their CD34$^+$ or CD133$^+$ progenitor cells using SCF and IL-6 can generate large numbers of functionally mature MCs that can be interrogated for various types of biologic investigations. Many studies of MCs and/or mastocytosis have relied on MC lines such as the SCF-dependent cell lines LAD1/LAD2, derived from patients with MC sarcoma (MCS) with *KIT* D816V (this cell line actually has normal *KIT* despite its origin, and is SCF-dependent); the LUVA cell line (derived from CD34$^+$ cells, growth factor–independent, normal *KIT*, and tendency to lose FcεRI expression with long-term culture); and the SCF-independent human MC line HMC-1 derived from a patient with MCL. Two HMC-1 subclones are available—HMC-1.1, which contains the *KIT* V560G mutation, and HMC-1.2, which expresses both *KIT* V560G and D816V. Both clones have been useful for in vitro evaluation of the differential sensitivity of different small-molecule inhibitors of KIT. None of these human MC lines, however, express both a functional IgE receptor and *KIT* D816V. However, a human cord blood–derived cell line that is SCF-dependent and FcεRI$^+$ (ROSA$^{\text{KIT WT}}$) has been developed which converts to SCF independence and produces tumors with transfection by *KIT* D816V (ROSA$^{\text{KIT D816V}}$), and is widely used as a tool for studying the biology and pharmacologic aspects of mastocytosis.[35] Other human MC lines that have been studied in the context of mastocytosis are LAD2, LADR, and MCPV-1.

Mouse Models to Study Human Mastocytosis

A number of murine models of mastocytosis are available, including several transgenic models and xenotransplantation models. First, all the cell lines described earlier have been applied successfully in xenotransplantation models. In most instances, NSG mice were employed. In addition, several transgenic models have been established. In one model, transgenic mice harboring a fusion transgene consisting of the 571-bp primate chymase gene (Δ571-bchm) promoter fragment and the human Kit proto-oncogene cDNA with the codon 816 Asp→Val substitution were generated. These mice were found to slowly develop a MC disease-like condition with focal accumulations of MCs in the spleen and other organs, resembling indolent SM (ISM). In another model, a transgenic mouse exhibiting murine KIT *D814V* was established. These mice developed GI MC accumulations. Both models may not reflect all aspects of the human disease, but may be helpful for future investigations.

FIP1L1::PDGFRA- and *NPM::ALK*-Based Murine Models

Expression of the *FIP1L1::PDGFRA* fusion alone in murine BM cells was not sufficient to cause eosinophilia, but only a general myeloproliferative syndrome.[36] However, overexpression of IL-5 together with *FIP1L1::PDGFRA* produced typical features closely resembling HES, including tissue infiltration by eosinophils.[37] However, a phenotype of mastocytosis in addition to eosinophilia developed in another murine model by introducing *FIP1L1::PDGFRA* into hematopoietic stem cells and progenitors with T-cell overexpression of IL-5.[38] Transplantation of *NPM::ALK* (nucleophosmin-anaplastic lymphoma kinase)–transduced progenitors into normal mice or IL-9–transgenic mice without *NPM::ALK* each result in MC hyperplasia; however, both "single-hit" models are insufficient to generate a histopathologic picture of SM.[39] SM is only observed when *NPM::ALK* is transduced into mouse BM progenitors of lethally irradiated IL-9 transgenic mice. Similar to the model of *FIP1L1::PDGFRA* and IL-5, this model of the *NPM::ALK* fusion and IL-9 highlights the biologic interdependence of a fusion oncogene and cytokine-related pathways in promoting the full expression of neoplastic MC growth.

Germline Susceptibility to Mast Cell Disorders and Familial Mastocytosis

In general, mastocytosis behaves as an acquired, somatic disease. However, several familial cases (more frequently presenting as cutaneous rather than systemic disease, and sometimes associated with GI stromal tumors [GIST]) have been reported. In most of these families, mutations in various codons of the *KIT* gene (e.g., K509I, A533D, W557R,V559A, V560del, D579del, K622E/T, D820Y, N822I, M835K, S849I, or deletion of amino acids 419 or 559–560) have been detected in the germline.[40–42] However, in a few families, the *KIT* mutation was only expressed in hematopoietic cells, but not in the germline of the affected individuals, suggesting that predisposing germline factors may contribute to disease development. However, so far, little is known about what gene polymorphisms serve as susceptibility alleles. In one study, polymorphisms within certain cytokine genes have been identified as exerting a potential predisposition to development of SM. In particular, a polymorphism in the promoter of the *IL-13* gene, −1112 C/T, was significantly more frequent in SM patients versus both cutaneous mastocytosis (CM) patients and healthy controls.[43] In addition −1112 C/T was associated with increased serum tryptase levels and adult-onset disease. MCs express IL-13 receptors and IL-13–containing medium provides enhanced support for the growth of MCs. However, it remains unclear how −1112 C/T relates to these specific biologic findings. In contradistinction to the IL-13 −1112 C/T germline allele, the *IL-4α* chain receptor Q576 polymorphism was associated with more limited forms of mastocytosis. IL-4 modulates the growth and differentiation of MCs, and induces IgE receptor expression in MCs.[44] Polymorphisms in the IL-4 receptor have been implicated in allergic and inflammatory conditions. In a study of patients with cutaneous and systemic forms of mastocytosis, this polymorphic allele was significantly more associated with cutaneous disease, childhood-onset disease, and lower levels of serum tryptase and soluble CD117. The Q576 polymorphism in the *IL-4α* chain receptor therefore appears to protect against MC hyperplasia and more aggressive forms of the disease. The Asp358Ala polymorphism in the *IL-6* receptor was associated with a 2.5-fold lower risk for mastocytosis compared with those with the AC or CC genotypes.[45] However, no association was found between the *IL-6* 174 G/C polymorphism and increased susceptibility to SM.

EPIDEMIOLOGY AND CLASSIFICATION OF MASTOCYTOSIS

In 2008, SM was included in the WHO category of myeloproliferative neoplasms (MPNs).[12] However, based on the complex clinical picture, biology, and pathology, SM was again defined by the WHO as a separate unique myeloid neoplasm in 2016. SM is an orphan disease and sparse data exist regarding its incidence or other epidemiologic features. A slight male predominance has been observed, and in one study, the median age at time of SM diagnosis was 55 years. A retrospective study from Denmark that canvassed the years from 1997 to 2010 estimated the incidence of SM at 0.89 per 100,000 persons per year, with an estimated prevalence of 9.59 per 100,000 individuals.[46] A Dutch analysis estimated the prevalence of ISM to be 13 cases per 100,000 inhabitants.[47]

The first diagnostic checkpoint is to distinguish SM from CM, which is characterized by predominant skin involvement. Criteria to diagnose SM are not fulfilled in these patients. However, in rare cases with CM, a discrete involvement of the BM by clonal cells may be detected, and serum tryptase levels may be slightly elevated. SM primarily occurs in adults, whereas CM is more common in children and its natural history is typically defined by spontaneous resolution of skin lesions usually at the time of puberty.[48] CM variants include urticaria pigmentosa/maculopapular CM, diffuse CM, and solitary mastocytoma of the skin.[12,49] In the overwhelming majority of adults with cutaneous involvement, systemic disease (SM) is diagnosed. However, absence of skin lesions does not exclude the presence of SM. Skin involvement occurs in over 80% of all patients with adult SM. However, sometimes no BM examination is performed for some time, especially when the patient has not been referred to a hematologist. In such cases, cutaneous lesions are referred to as *mastocytosis in the skin* (MIS).

Diagnostic criteria for SM were initially formulated by a working group of MC disease experts at a consensus conference in Vienna in 2000,[11] and adopted by the WHO in both 2001[50] and 2008.[12] In 2022, the WHO[51a] and International Consensus Classification (ICC)[51b] generated some minor modifications to the classification of SM and its variants. Minimal diagnostic criteria for SM requires at least one major plus one minor criterion, or at least three minor criteria (Table 75.2). The major criterion is the presence of multifocal dense aggregates of MCs (>15 MCs in aggregates) in sections of BM or other extracutaneous organ(s); minor criteria include: (1) >25% of the MCs in the infiltrate or in the BM smear are of spindle shape or of otherwise atypical morphology; (2) activating mutation at codon 816 in the *KIT* gene (or other activating *KIT* mutation) in an extracutaneous organ; (3) expression of CD25 +/− CD2 or CD30 in/on MCs (2022 WHO and ICC modifications); and (4) serum tryptase level >20 ng/mL, unless there is an associated myeloid disorder that makes this parameter not valid.[51]

SM is further divided into several subtypes that reflect the presence or absence of certain clinical or laboratory findings (Tables 75.3 and 75.4). The most common form of SM in adults is ISM, characterized by a slightly to markedly increased burden of neoplastic MCs in the BM and/or other extracutaneous organ(s). By definition, ISM patients do not exhibit MC-related organ damage or an associated

TABLE 75.2 **2022 World Health Organization and International Consensus Classification (ICC) Diagnostic Criteria for Systemic Mastocytosis**[a]

Major criterion	Multifocal dense infiltrates of mast cells (>15 mast cells in aggregates) detected in sections of bone marrow and/or other extracutaneous organ(s)
Minor criteria	a. In biopsy sections of bone marrow or other extracutaneous organs, >25% of the mast cells in the infiltrate are spindle shaped or have atypical morphology or, of all mast cells in bone marrow aspirate smears, >25% are immature or atypical b. Detection of an activating point mutation at codon 816 in *KIT* (or other activating *KIT* mutation in bone marrow, blood, or another extracutaneous organ) c. Mast cells in bone marrow, blood, or other extracutaneous organs express CD25 with or without CD2 or CD30 in addition to normal mast cell markers d. Serum total tryptase persistently exceeds 20 ng/mL (unless there is an associated clonal myeloid disorder, in which case this parameter is not valid)

[a] Requires at least 1 major + 1 minor criterion or 3 minor criteria.

TABLE 75.3 2022 World Health Organization Variants of Mastocytosis

Cutaneous mastocytosis (CM)

a. Maculopapular CM
b. Diffuse CM
c. Mastocytoma of skin

Systemic mastocytosis (SM)

a. Indolent systemic mastocytosis (ISM)
b. Bone marrow mastocytosis (BMM)[a]
c. Smoldering systemic mastocytosis (SSM)
d. Aggressive systemic mastocytosis (ASM)
e. Systemic mastocytosis with an associated hematologic neoplasm (SM-AHN)[b]
    SM-MDS
    SM-MPN (e.g., PV, ET, MF, CML)
    SM-MDS/MPN (e.g., CMML, MDS/MPN-unclassifiable)
    SM-CEL
    SM-AML
f. Mast cell leukemia (MCL)
    Aleukemic vs. leukemic MCL
    Chronic vs. acute MCL
    Primary vs. secondary MCL
    MCL with or without an AHN

Mast cell sarcoma (MCS)

[a] In the 2022 WHO Classification and 2020 Working Conference consensus proposal, BMM is a separate category from ISM; in the International Consensus Classification (ICC), it remains a subtype of ISM.[57a] BMM is a separate category from ISM. It is defined the same as ISM but without skin lesions and is typically characterized by lower tryptase levels and absence of both B and C findings.

[b] The table shows typical examples of SM-AHN. Most AHN are myeloid neoplasms.

AML, Acute myeloid leukemia; *CEL, NOS*, chronic eosinophilic leukemia, not otherwise specified; *CLL*, chronic lymphocytic leukemia; *CML*, chronic myeloid leukemia; *CMML*, chronic myelomonocytic leukemia; *ET*, essential thrombocythemia; *MDS*, myelodysplastic syndrome; *MF*, myelofibrosis; *MPN*, myeloproliferative neoplasm; *NHL*, non–Hodgkin lymphoma; *PV*, polycythemia vera.

TABLE 75.4 2022 World Health Organization Diagnostic Criteria for Variants of (Systemic) Mastocytosis

1. **Indolent systemic mastocytosis (ISM):** Meets criteria for SM. No "B" or "C" findings. No evidence of associated clonal hematologic malignancy/disorder. In this variant, the mast cell burden is usually low; skin lesions are almost invariably present.
2. **Bone marrow mastocytosis:** As above, but no skin lesions and a serum tryptase level <125 ng/mL with bone marrow involvement, but no skin lesions.
3. **Smoldering systemic mastocytosis (SSM):** Meets criteria for SM. Two or more "B" findings and no "C" findings.
4. **Systemic mastocytosis with an associated hematologic neoplasm (SM-AHN):** Meets criteria for SM and criteria for an associated hematologic neoplasm (MDS, MPN, MDS/MPN, CEL, AML, lymphoma, or other hematologic neoplasm that meets the criteria for a distinct entity in the WHO classification).
5. **Aggressive systemic mastocytosis (ASM):** Meets criteria for SM. One or more "C" findings. No associated clonal hematologic neoplasm. No evidence of mast cell leukemia.
6. **Mast cell leukemia (MCL):** Meets criteria for SM. Bone marrow biopsy shows diffuse infiltration, usually interstitial pattern, by atypical, immature mast cells. Bone marrow aspirate smears show 20% or more mast cells. Cases in which <10% of circulating WBCs are mast cells are referred to as "aleukemic mast cell leukemia."
7. **Mast cell sarcoma (MCS):** Unifocal mast cell tumor. No evidence of SM. No skin lesions. Destructive growth pattern. High-grade cytology.

AML, Acute myeloid leukemia; *CEL*, chronic eosinophilic leukemia; *MDS*, myelodysplastic syndrome; *MPN*, myeloproliferative neoplasm; *SM*, systemic mastocytosis; *WBC*, white blood cell; *WHO*, World Health Organization.

hematologic disorder, and life expectancy in this variant has been shown to be similar to that of an age-matched healthy population,[52] with an analysis showing a 10-year overall survival (OS) of 93.5% (Fig. 75.1).[53] However, ISM patients often experience mediator symptoms related to MC degranulation (e.g., flushing, pruritis, diarrhea, abdominal cramping, neuropsychiatric complaints). Although triggers may not always be identifiable, known provokers of MC activation and/or anaphylaxis include non-IgE and IgE-mediated causes: physical or emotional stress, exercise, hot or cold temperature stimuli, medications such as aspirin, NSAIDs, opioid analgesics, or antibiotics, alcohol, radiocontrast dye, and IgE-mediated allergies. One critical comorbidity is Hymenoptera (e.g., wasps, bees, and ants) venom allergy. In particular, these patients are at high risk of developing severe or even fatal anaphylaxis upon exposure to the venom. Cutaneous involvement usually develops in conjunction with the ISM subtype, both in younger individuals as well as in older patients. However, those with advanced disease may also develop MIS. Interestingly, skin disease usually portends a decreased risk of anaphylaxis, especially due to Hymenoptera stings.[54,55] Bony disease (e.g., localized bone pain, diffuse osteopenia, osteoporosis with or without pathologic fractures, osteosclerosis) is also well described in ISM, but can cause morbid complications across the spectrum of SM variants.[56,57] Bone marrow mastocytosis (BMM) is defined similarly as ISM but without skin lesions and typically exhibits lower tryptase levels, e.g. <125 ng/mL. It is listed as a subtype of ISM the 2016 WHO diagnostic criteria, but as a separate category in the 2020 Working Conference consensus proposal of mastocytosis.[57a]

In the 2008 WHO classification, smoldering SM (SSM) was designated as a subvariant of ISM. However, based on the current classification proposed by the consensus group, SSM was included in the revised 2016 WHO classification as a separate variant of SM, which is meaningful because these patients exhibit a higher chance of progression to more advanced disease.[12,51,52,58–60] SSM is defined by two or more "B" findings (Table 75.5), for example, (1) hepatomegaly without impairment of liver function, and/or palpable splenomegaly without hypersplenism, and/or lymphadenopathy on palpation or imaging; (2) BM MC burden >30% and serum tryptase level >200 ng/mL; and (3) signs of dysplasia or myeloproliferation, in non-MC lineage(s), but insufficient criteria for definitive diagnosis of an additional hematopoietic neoplasm, with normal or only slightly abnormal blood counts.[12,51,52] Compared with ISM, SSM patients often exhibit clonal multilineage involvement with the *KIT* D816V mutation, which is also a prognostically relevant variable.[61,62] In the 2022 WHO classification, a KIT D816V variant allele frequency ≥10% qualifies as a "B" finding.

Advanced SM (AdvSM) is an umbrella term for three variants that are characterized by decreased life expectancy: SM with an associated hematologic neoplasm (SM-AHN), aggressive SM (ASM), and MCL. SM-AHN comprises 30% of SM variants,[63] and approximately two-thirds of advSM cases, although this figure may vary depending on referral patterns. In the revised 2016 WHO classification, the term "SM-AHN" can be used interchangeably with or in lieu of the prior term "SM-AHNMD" (SM with an associated hematologic non-MC lineage disease).[51] The vast majority of AHNs are myeloid neoplasms: myelodysplastic syndrome (MDS), MPNs, MDS/MPN overlap disorders such as chronic myelomonocytic leukemia (CMML) or MDS/MPN-unclassifiable, chronic eosinophilic leukemia, not otherwise specified (CEL, NOS), and acute myeloid leukemia (AML).[64,65] Rarely, lymphoid neoplasms such as chronic lymphocytic leukemia, myeloma, or lymphomas have been found in association with

Figure 75.1 OVERALL SURVIVAL AND PROGRESSION-FREE SURVIVAL OF PATIENTS WITH MASTOCYTOSIS ACCORDING TO THE INTERNATIONAL PROGNOSTIC SCORING SYSTEM FOR MASTOCYTOSIS (IPSM). Overall survival was determined in all patients in whom the score could be calculated. Mast cell leukemia, the most aggressive mast cell disorder (cannot progress into a more aggressive variant) and mastocytosis in the skin, a provisional diagnosis for patients with proven skin involvement but unknown/unavailable bone marrow results, were excluded from analysis of progression-free survival. Overall survival (A) and progression-free survival (B) were estimated according to the method of Kaplan and Meier. In these analyses, patients with Low, Intermediate (Int)-1, and Int-2 risk groups differed significantly in their overall survival and progression-free survival and had a favorable outcome compared to patients with advanced systemic mastocytosis (AdvSM) according to log rank test ($P < .0001$). Estimated overall survival (C) and progression-free survival (D) according to the IPSM for patients with AdvSM. overall survival and progression-free survival differed significantly between the cohort without risk factors (AdvSM-1), patients with one risk factor (AdvSM-2), those with two to three risk factors (AdvSM-3), and those with four to five risk factors (AdvSM-4) ($P < .0001$). The overall survival of patients in the risk groups AdvSM-1 and AdvSM-2 were similar to that of non-advanced mastocytosis patients in the int-1 and int-2 risk group, respectively. *AdvSM*, Advanced systemic mastocytosis.

TABLE 75.5 **"B" Findings: Indication of High Mast Cell Burden**[a]

1. Bone marrow mast cell burden >30% by histology and serum tryptase level >200 ng/mL
2. Hypercellular marrow with loss of fat cells, discrete signs of dysmyelopoiesis without substantial cytopenias, and without WHO criteria for an MDS or MPN
3. Organomegaly: palpable hepatomegaly, splenomegaly, or lymphadenopathy (on CT or ultrasound) >2 cm without impaired organ function

[a] In the 2022 WHO 5th edition. a KIT d816V variant allele frequency ≥10% qualifies as a "B" finding.

MDS, Myelodysplastic syndrome; *MPN*, myeloproliferative neoplasm; *WHO*, World Health Organization.

SM.[66,67] Identifying a concomitant myeloid neoplasm may depend on several factors, including the expertise of the evaluating pathologist, and whether one disease is masked by the presence of another. For example, in cases of SM-AML, MC aggregates may only be unmasked after induction chemotherapy with achievement of BM hypoplasia, because neoplastic MCs may persist after such therapy.[68,69] Distinguishing nonhematologic or hematologic organ damage due to the SM component versus the associated myeloid disease can be very difficult, if not impossible, in some patients. Even when a biopsy of the involved extramedullary organ is analyzed to elucidate the burden of neoplastic MCs versus associated myeloid neoplasm, it is sometimes impossible to define the relative impact of the SM versus AHN component on organ dysfunction, especially when both disease components are of an aggressive type.

Although the prognosis of SM-AHN frequently relates to the AHN component, the burden of SM as well as the type and stage of the associated myeloid neoplasm need to be considered on an individual basis. Treatment plans are tailored to the histopathologic and molecular findings and the clinical sequelae that are felt to be attributable to each disease component. A commonly cited therapeutic approach has been to treat the SM component as if the myeloid neoplasm were not present, and to treat the myeloid neoplasm as if

TABLE 75.6 **"C" Findings: Indication of Organ Damage Attributable to Neoplastic Mast Cell Infiltration**

1. Cytopenia(s): Absolute neutrophil count <1 x10^9/L or hemoglobin <10 g/dL or platelets <100 x10^9/L
2. Hepatomegaly with ascites and/or impaired liver function
3. Palpable splenomegaly with hypersplenism
4. Malabsorption with hypoalbuminemia and weight loss
5. Skeletal lesions: large-sized osteolyses (≥2 cm) and/or pathologic fractures
6. Life-threatening organopathy in other organ systems that is definitively caused by an infiltration of the tissue by neoplastic mast cells

SM were not present.[70–72] Because the *KIT* D816V mutation may be present in the cells belonging to both disease compartments,[73] small molecule inhibitors of dysregulated KIT may provide benefit for both the SM and AHN in selected cases.

ASM comprises 5% to 10% of SM variants and is defined by one or more "C findings" (Table 75.6) reflecting organ dysfunction because of neoplastic MC infiltrates.[12,13,51,70–72] Examples of C findings include marked cytopenias because of extensive BM involvement (defined by an absolute neutrophil count [ANC] $<1 \times 10^9$/L, hemoglobin <10 g/dL, and/or platelet count $<100 \times 10^9$/L) and/or hypersplenism; hepatomegaly with liver dysfunction, and/or portal hypertension or ascites; hypoalbuminemia, which may relate to liver dysfunction and/or gut infiltration by neoplastic MCs; weight loss; and severe bone disease manifested by large osteolyses (≥ 2 cm) and/or pathologic fractures. In a majority of patients with ASM, the percentage of MCs in the BM smear is below 5%, which is a favorable prognostic sign. Notably, in the less frequent ASM patients in whom MCs comprise ≥5% of all nucleated BM cells on a Giemsa-stained BM smear, the prognosis is poor, as many of these patients progress and transform to MCL or an ASM-AHN. Therefore these patients have recently been described as ASM in transformation (ASM-t; see later also under diagnostic evaluation of mastocytosis).[74] As soon as the percentage of MCs in these patients increases to ≥20% in the BM smear, the diagnosis changes to MCL.

MCL is a very rare form of SM (~1% of SM variants) and is defined by MCs comprising ≥20% of nucleated cells on BM aspirate smears.[12,51,74] On the core biopsy, MCs form a diffuse, compact infiltrate with usually low levels of fibrosis. High-grade cytologic features of MCs can be observed in MCL, including multilobed or clefted nuclei, clumping of metachromatic granules, metachromatic blasts (rare, more typical for myelomastocytic leukemia), and, rarely, mitotic figures. In MCL, circulating MCs (≥10% of nucleated cells) may be found; however, the aleukemic MCL variant (<10% MCs in the peripheral blood) is more common.[12,51] MCL may arise de novo or progress from less advanced forms of SM, such as ASM with elevated MC counts on the BM aspirate. MCL typically has a dismal prognosis with a life expectancy of 6 months or less in most patients,[75] but survival can be heterogeneous, extending to 1 to 2 years or longer, and can be adversely impacted by high-risk mutations involving *SRSF2*, *ASXL1*, and/or *RUNX1*.[76] A chronic form of MCL has also been described, wherein patients meet histopathologic criteria for the disease, but without C findings (see later). In these cases, MCs tend to show a more mature morphology, and may exhibit imatinib-sensitive JM *KIT* mutations.[74,77–80] However, even those with the initially more indolent form of (chronic) MCL are expected to show progression over time with development of organ damage (transformation to acute MCL) and limited survival. In addition to the distinction of MCL into acute and chronic forms, and the historical convention of dividing MCL into leukemic and aleukemic variants, other useful subclassifications include MCL with or without an AHN, and primary (de novo) versus secondary MCL,[76] the latter transformed from less advanced disease or MCS.

MCS is a rare MC tumor that can invade local tissues and has a high potential to develop advanced systemic disease with a fulminant course.[81] In particular, most if not all patients with MCS progress to MCL within a relatively short time period. Vice versa, MCS-like tumors ("secondary MCS") may develop during the course of SM, usually the advanced forms. Extracutaneous mastocytoma is another rare SM variant that typically follows a benign course.[82] However, because of its rarity, this MC disease entity was eliminated from the last update of the WHO classification.[51]

Well-differentiated SM (WDSM) is a more recently described rare variant of SM that is not yet formally recognized by the WHO (see later for histopathologic characteristics). The major reason for this is that the well-differentiated (WD) morphology of MCs can be found in all WHO subvariants of SM, including ISM, ASM, and MCL.[77–80] Therefore the WD phenotype should be used as a descriptive term to complement the WHO diagnosis rather than as a tool to formulate a new entity.

Mast Cell Activation Syndromes

Diagnostic criteria and a classification have been formulated for MC activation syndromes (MCAS) by the consensus group.[83–85] MCAS are clinical conditions defined by MC activation but are not regarded as subtypes of SM (Table 75.7).[83–85] Patients with MCAS exhibit symptoms (e.g., anaphylaxis) and/or biochemical evidence of massive MC degranulation, with an event-related increase in serum tryptase. Other mediators produced by MCs may also increase during anaphylaxis. These mediators include plasma histamine, and spot or 24-hour urine *N*-methylhistamine, PGD2 or metabolite 11-beta PGF2. Several different variants of MCAS have been described (Table 75.8). In patients with reactive MCAS, an underlying allergy is most commonly detected, whereas no signs of MC clonality are found. By contrast, in patients with primary (clonal) MCAS, MC monoclonality can be demonstrated. In these patients, MCs in the BM may be increased, often with atypical morphology, and evidence for their clonality can be established by identification of *KIT* D816V or cell surface expression of CD25.[86,87] In patients with primary MCAS, there are two subsets of patients. One group of patients fulfills the criteria of an underlying MC disease, usually in form of SM (criteria to diagnose SM are fulfilled). In the second group of patients, the burden of MCs is very low, and despite the documented presence of clonal MCs, neither SM nor CM can be

TABLE 75.7 **Criteria for the Diagnosis of Mast Cell Activation Syndrome**

A. Typical symptoms (see below) that are related to two organ systems
B. Increase in serum total tryptase by at least 20% above baseline plus 2 ng/mL during or within 4 h after a symptomatic period
C. Response of clinical symptoms to histamine receptor blockers or MC-targeting agents, e.g., cromolyn

Typical Symptoms

Flushing
Pruritis
Urticaria
Angioedema
Nasal congestion
Nasal pruritis
Wheezing
Throat swelling
Headache
Hypotension
Diarrhea

MC, Mast cell.

TABLE 75.8 Classification of Mast Cell Activation Syndromes

Category and Variants	Proposed Criteria
Primary MCAS = (mono)clonal MCAS	MCA criteria fulfilled and MC (mono) clonality proven ($CD25^+$ MC and/or *KIT* D816V)[a]
• Mastocytosis • Primary MCAS without evidence of mastocytosis	
Secondary MCAS	MCA criteria fulfilled and criteria for the diagnosis of allergy or other diseases that can produce MCA fulfilled as well
• Allergy • Other underlying disorder[b]	
Idiopathic MCAS[c]	MCA criteria fulfilled, but no disease that could lead to MCA diagnosed

[a] $CD25^+$ MCs plus *KIT* D816V detectable, or *KIT* D816V detectable, but MCs cannot be demonstrated to express CD25.
[b] Disorders associated with MCA include autoimmune diseases, certain bacterial infections, and some adverse drug reactions.
[c] Idiopathic MCAS is a final diagnosis but needs an extensive workup in order to exclude all potential underlying conditions. Idiopathic and secondary MCA episodes may occur at different time points in the same patient.
MC, Mast cell; *MCA*, mast cell activation; *MCAS*, mast cell activation syndrome.
From Valent P, Akin C, Arock M, et al. Definitions, criteria and global classification of mast cell disorders with special reference to mast cell activation syndromes: a consensus proposal. *Int Arch Allergy Immunol.* 2012;157:215.

diagnosed. In these patients, one or two minor SM criteria are typically present. However, at the time of diagnosis, a diagnosis of an underlying MC disease cannot be established.[84] In both instances, the diagnosis is primary (clonal) MCAS. Because of the very low numbers of MCs, techniques to enrich for MCs and/or use of sensitive techniques to detect *KIT* D816V (e.g., allele-specific PCR) may be necessary to detect neoplastic MCs in these patients. Currently, there is no evidence that these two entities are "prodromal" SM conditions with a defined rate of progression to systemic MC disease. If neither an underlying allergy or another underlying reactive process nor a clonal population of MCs can be detected in an MCAS patient, the final diagnosis is idiopathic MCAS.[84] Criteria for MCAS include an event-related increase in serum tryptase, typical symptoms related to at least two organ systems, and response of these symptoms to drugs targeting MC activation, MC-derived mediators, or their specific receptors.[84] All three MCAS criteria must be fulfilled to characterize the condition as MCAS. The minimal increase in tryptase is defined by the following formula: 20% of baseline plus absolute 2 ng/mL.[88] Example: if in an SM patient with 100 ng/mL baseline tryptase, an anaphylactic response to a bee sting is followed by an increase to 150 ng/mL, the reaction is called MCA ($100 + 20 + 2 = 122$; this means any value above 122 qualifies as a MCAS criterion). It is important to know that after such an anaphylactic reaction, it takes at least 24 to 48 hours (after complete resolution of symptoms) until the baseline of tryptase is again reached.

In patients with IgE-mediated hymenoptera venom anaphylaxis, particularly individuals with an elevated baseline tryptase level (separate from the acute rise after a sting), the suspicion for an underlying clonal MC disorder is increased.[89–92] The differential diagnosis for MCAS includes allergic disorders resulting in secondary MC activation such as chronic urticaria/angioedema, exposures to certain foods, drugs, or environmental allergens, physical or temperature stimuli (exercise-induced anaphylaxis; cold or cholinergic or delayed-pressure urticaria), asthma, and idiopathic anaphylaxis.[93]

An autosomal dominant genetic condition called hereditary alpha-tryptasemia (HαT) has also been described.[94] In these patients, extra copies of the human tryptase alpha gene, *TPSAB1*, are found. The genetic trait is characterized by slightly elevated basal serum tryptase levels, cutaneous flushing and pruritus, connective tissue abnormalities, symptoms suggestive of autonomic dysfunction, vibration-induced reactions, and a certain risk for severe immediate hypersensitivity reactions, especially when an allergy and/or a MC disease is also present. Although the mechanisms are not completely understood, HαT should be regarded as a potential risk factor for severe mediator-related symptoms in patients with MC disorders.[95,96]

Diagnostic Evaluation of Mastocytosis

Tissue biopsy in conjunction with clinical and pathology expertise are critical in establishing the diagnosis of SM. BM MC burden is best quantified by morphologic analysis and immunohistochemical stains such as tryptase, CD117 (KIT), and CD25 on the core biopsy.[12,13,51,97] Multiparameter flow cytometric analysis of BM aspirates can also be used to quantify the percentage of MCs, and generally correlates with SM burden defined by morphologic/immunohistochemical evaluation.[98,99] Morphologic evaluation of the BM aspirate is additionally important for evaluating dysplasia and excess myeloblasts, and most relevant to MCL, the number of atypical MCs. Based on this evaluation, the presence of MCL can be excluded or can be confirmed during the diagnostic work-up.

The most important morphologic feature of mastocytosis, in particular its systemic variants, is the presence of compact infiltrates consisting of densely packed atypical MCs.[12,51] Compact MC infiltrates are almost never detected in reactive states, even in those with marked MC hyperplasia. Accordingly, compact MC infiltrates can be regarded as the only major criterion for diagnosis of mastocytosis, which also underlines the important role of the hematopathologist in making these diagnoses. Investigation of an adequate BM biopsy trephine specimen is crucial to assess or exclude a diagnosis of SM. In most patients a few compact infiltrates can be identified even by using conventional stains like Giemsa-Wright or toluidine blue, which both facilitate detection of the pathognomonic metachromatic granules.[12,51] The MCs are round or spindle shaped, and often exhibit at least some hypogranulation. The nuclei are round or elongated depending on the shape of the cell. Prominent nucleoli are not seen. Almost always such compact infiltrates also contain mature eosinophils, histiocytes, and sometimes large follicle-like aggregates of

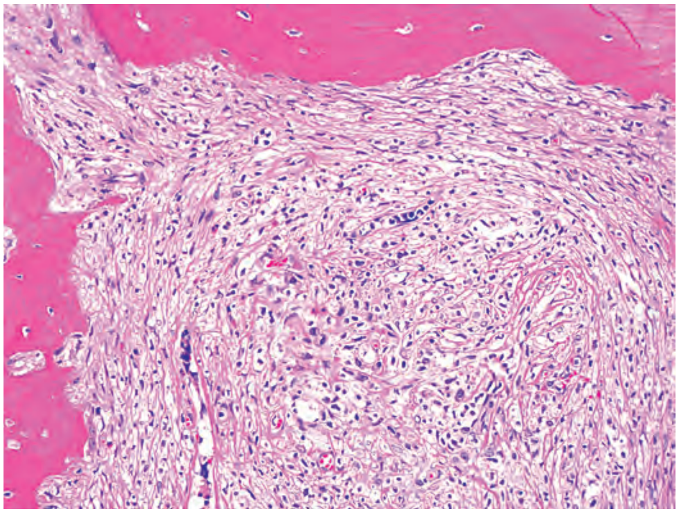

Figure 75.2 AGGRESSIVE SYSTEMIC MASTOCYTOSIS (SM). Core biopsy, hematoxylin, and eosin stain. Extremely hypercellular bone marrow with subtotal depletion of fat cells and normal blood cell precursors. Packed infiltration by atypical hypogranulated spindle-shaped mast cells that are embedded in a dense fibrotic stroma is the typical finding in aggressive systemic mastocytosis (ASM). However, only the presence of C-finding(s) qualifies such cases to be subtyped as ASM. Similar pictures can be seen in smoldering systemic mastocytosis with "B" findings. Note that the morphologic features of nonspecific fibrosis or granulation tissue may be very similar and appropriate immunostaining is necessary to confirm the diagnosis of SM.

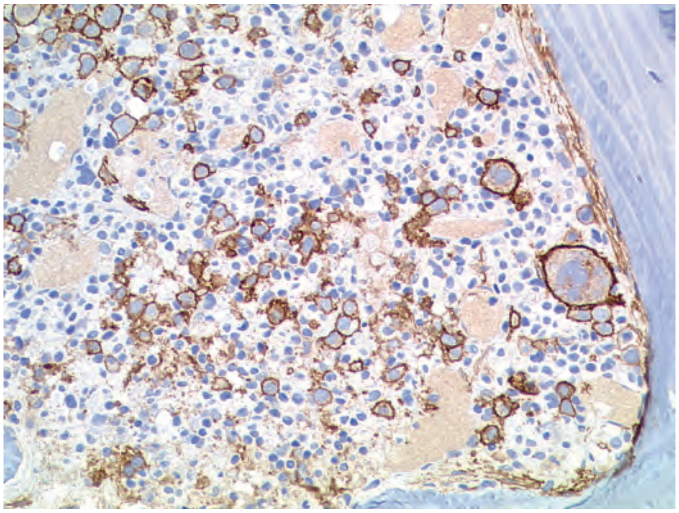

Figure 75.3 ACUTE MAST CELL LEUKEMIA WITH CD30 EXPRESSION. Core biopsy with positive staining of mast cells for surface CD30. Bone marrow section shows extreme hypercellularity with diffuse-packed infiltration by atypical round mast cells coexpressing tryptase and CD117 (not depicted). A significant number of the mast cells stain positive by an antibody against CD30, among them a few multinucleated giant cells that resemble Reed-Sternberg cells. A diagnosis of Hodgkin lymphoma should not be established in such cases.

lymphocytes that are polyclonal in nature. Reticulin fiber density is always increased with the exception of a few very small but diagnostic infiltrates. Larger compact and mixed infiltrates often show patchy collagen fibrosis. The degree of reticulin fibrosis in most cases of MCL is low, which can be used as a criterion that allows one to distinguish MCL from ASM, which usually exhibits marked reticulin or even collagen fibrosis (Fig. 75.2).[12,51] Immunohistochemistry should be performed in all cases in order to enumerate the numbers of loosely scattered MCs and to detect small but diagnostic compact infiltrates. The degree of MC infiltration should always be documented by the hematopathologist: it is recommended to refer to the section area and to the overall cellularity in this respect. This enables monitoring of the disease during and after therapy. MCs almost always coexpress tryptase and CD117; in most SM cases, MCs also aberrantly express CD25, whereas aberrant expression of other antigens such as CD2 is more rarely encountered and therefore of minor diagnostic importance (Fig. 75.3). Interestingly, it could be shown that MCs may lose immunohistochemically detectable CD25 or tryptase expression during or after therapy with TK inhibitors such as midostaurin,[100] and MCs in cases of intestinal involvement by SM may lack detectable tryptase expression at diagnosis (e.g., incomplete immunophenotype). However, it can be stated definitively that a cell lacking expression of CD117 (KIT) cannot be a MC. Although ISM and isolated mastocytosis of the BM (BMM) usually show a minor degree of BM involvement with multifocal compact infiltrates (<10% of the section area), smoldering and advSM but also MCL usually exhibit a more diffuse or packed infiltration occupying more than 30% and up to 100% of the section area. In a significant proportion of cases compact MC infiltrates are missing and the degree of tissue involvement may be very low (<1% regarding cellularity and section area). Accordingly, such cases could be termed "occult SM," and are difficult to detect for the pathologists. Moreover, SM is a great mimicker with regard to morphologic and immunophenotypical features of MCs, and a broad spectrum of differential diagnoses should be considered. The following list only contains the main entities and is therefore incomplete:

1. monocytic leukemias (clear cell feature + CD14)
2. histiocytoses (clear cell feature + CD68)
3. clear-cell carcinomas (clear cell feature + epithelial antigens like keratin)
4. basophilic leukemias (metachromatic granules + tryptase but missing CD117)
5. myelomastocytic leukemia (metachromatic blasts + tryptase + CD117)
6. Hodgkin lymphoma (CD30)
7. hairy cell leukemia (clear cell feature + CD25)
8. granulation tissue and scars

Evaluation of blood and BM smears is crucial for both identification and subtyping of MCL and separation of MCL from a recently described subtype of ASM, namely ASM-t (see earlier). In almost all patients with ISM and SSM, but also in most cases with ASM, the MC numbers in BM smears are lower than 5%, in ISM and SSM usually even below 1%. Crushed particles with higher numbers of MCs must not be considered in this respect. In a few patients with ASM the number of MCs is unusually high, exceeding 5% but not 19% of all nucleated cells. It is this subgroup of patients that has a worse prognosis but do not fulfill criteria for MCL and have therefore been termed ASM-t.[74]

Cytomorphologic findings in SM include atypically shaped MCs with spindled appearance (type I) on the one hand and round immature MCs with bilobated or monocytoid nuclei on the other (type II).[12,51] Atypical type I MCs are usually encountered in ISM, SSM, and often also in ASM, but also in isolated BMM, whereas atypical type II MCs dominate the picture in most cases of MCL, and are often found also in patients with ASM and ASM-t. Exceedingly rare cases of MCL with predominance of spindle-shaped cells of type I are associated with a relatively good prognosis and the disease accordingly has been termed *chronic MCL* (see earlier) (Fig. 75.4).[74,77] There is one peculiar phenotypic variant of SM termed *WDSM* (see earlier) that consists exclusively of round hypergranular-appearing MCs that form the typical cohesive clusters in BM smears.[78,79] Such MC clusters are not seen in all of the subvariants of SM. The feature of WDSM has been encountered in almost all defined subvariants of SM including MCL. WDSM usually lacks aberrant expression of CD25 and does also not show the typical activating point mutations at codon 816 of *KIT*, but instead the aforementioned JM *KIT* mutations which often exhibit sensitivity to imatinib (Fig. 75.5).[78,80] In addition, MCs in WDSM usually express CD30 which can be employed as additional disease indication (criterion) in these patients.

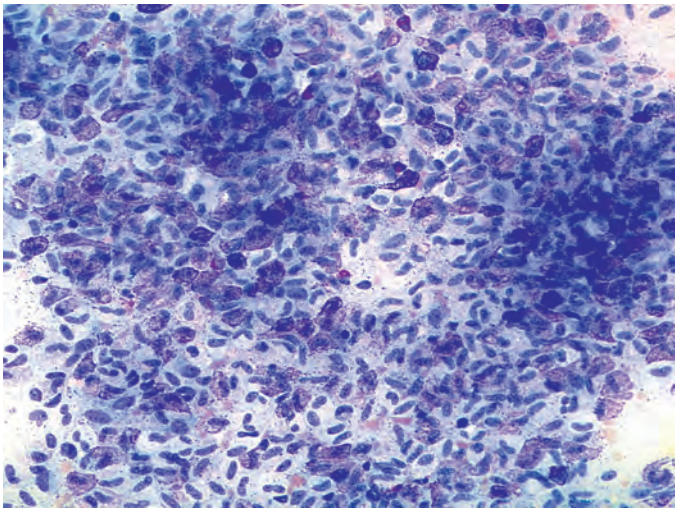

Figure 75.4 CHRONIC MAST CELL LEUKEMIA (BY CLINICAL BEHAVIOR). Bone marrow aspirate (Pappenheim stain) shows a very unusual picture with an extreme increase of spindle-shaped and often slightly hypogranulated mast cells. Note their elongated nuclei. Nucleoli are inconspicuous. Mast cell number is almost 100% and a diagnosis of mast cell leukemia can easily be established. The prolonged survival of this patient and the unique cytomorphologic aspect qualifies this case to be subtyped as chronic mast cell leukemia.

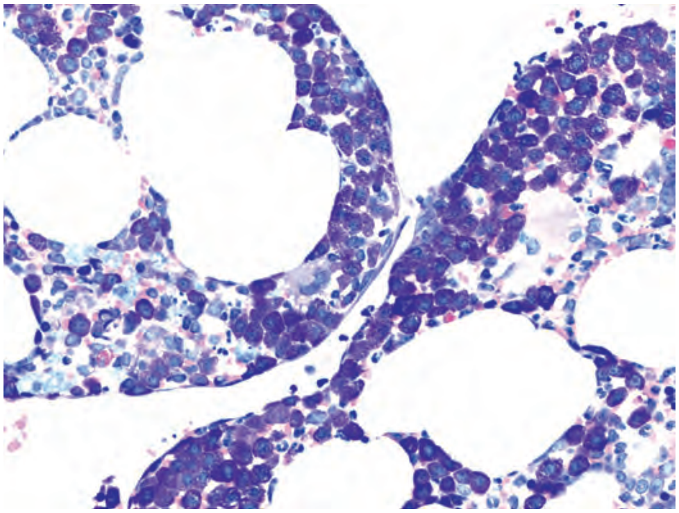

Figure 75.5 WELL-DIFFERENTIATED SYSTEMIC MASTOCYTOSIS. Core biopsy, Giemsa stain. Bone marrow shows aggregates of exclusively round mast cells with an abundance of metachromatic granules. This is the typical phenotypical appearance of a well-differentiated systemic mastocytosis. The disease was otherwise subtyped as indolent systemic mastocytosis with skin involvement but missing *KIT* D816V mutation and also lack of CD25 expression by the mast cells (not depicted).

CD30 (Ki-1) is a cytoplasmic and membrane-bound antigen expressed by neoplastic cells in Hodgkin lymphoma and anaplastic large-cell lymphoma. However, CD30 has also been shown to be expressed by neoplastic MCs in SM.[101,102] Although the antigen was originally reported as an immunohistochemical marker that is primarily expressed in the cytoplasm of MCs in more advanced forms of SM,[102] other studies have detected CD30 by immunohistochemistry in less advanced forms of MC disease, including CM, as well as ISM and SSM.[103–106] CD30 is not only expressed in the cytoplasm of neoplastic MCs but also on the cell surface, which has clinical implications as a CD30 antibody-toxin conjugate is available and was tested in a phase II trial of patients with CD30$^+$ advSM.[107] More recently, it was found that neoplastic MCs express higher levels of CD44 compared to normal MCs and that the levels of measurable CD44 on MC and in the plasma of patients with SM correlates with aggressiveness of the disease.[108]

Altogether, a complete diagnosis of SM reported by the hematopathologist should read like this:

SM-AHN; SM shows a marked multifocal BM infiltration (>50% section area) and is best subtyped as ASM since there is a reported C-finding and MC numbers in BM smears are low; AHN is a myeloid neoplasm that cannot be subtyped with certainty but morphological features are consistent with a disorder of the MDS/MPN category (MDS/MPN-unclassifiable).

Serum Tryptase Level

Tryptase is considered to be a most reliable and robust initial parameter with which to screen patients with suspected SM.[109–111] Tryptase is a serine protease primarily produced by MCs, and to a lesser extent by mature basophils and myeloid progenitors.[112–116] Commercially available ELISA-based assays measure total serum tryptase levels which consist of both mature tryptase (β-tryptase) and protryptases (e.g., α-tryptase).[117] The basal serum tryptase level reflects the MC burden in healthy individuals as well as in patients with SM, whereas the event-related (further) increase in tryptase is a marker of MC activation. β-tryptase is stored in MCs and released together with all other granular substances upon degranulation/anaphylaxis (tryptase levels peak 1 to 2 hours after degranulation event and return to baseline after 24 to 48 hours); the α-tryptase form is constitutively produced by MCs and thus more reflects the total burden of MCs.[115,118,119] For many centers, the upper normal reference range for the serum tryptase level is 10 or 11.4 ng/mL. However, healthy individuals may exhibit levels in the range of 5 to 15 ng/mL or higher, which may be confounded by tryptase haplotype, sex, and by the association between advancing age and increasing serum tryptase levels.[120,121] Although a serum tryptase level >20 ng/mL serves as a minor diagnostic criterion for SM, a minority of patients with histopathologically proven SM can exhibit values lower than this threshold.[12,51,109,122,123] In adult patients with MIS or hymenoptera allergy, a serum tryptase level >20 ng/mL is suggestive of the presence of SM.[54,122,124–126] Conversely, patients with CM usually exhibit a serum tryptase level <20 ng/mL, or it may be within normal range.[122,124,127] Other medical conditions besides SM and anaphylaxis that can produce an elevated tryptase level include renal failure, chronic helminth infections (MC hyperplasia), SCF treatment, and myeloid neoplasms, including MDS, MPN, AML, and CEL—notably patients with the *FIP1L1::PDGFRA* fusion gene.[128–135]

With the diagnosis of HαT, germline duplications and triplications in the *TPSAB1* gene encoding α-tryptase segregate with the inherited increase in basal serum tryptase and aforementioned systemic signs and symptoms.[94] As basal serum tryptase levels are elevated in 4% to 6% of the general population, and the clinical presentation of HαT can overlap with MCAS or systemic mastocytosis, it should be considered in the differential diagnosis of individuals presenting with an elevated tryptase level.[95,96]

Although there is a close correlation between high tryptase levels and advSM,[12,51,52,65,127] serum tryptase levels do not necessarily reflect the aggressiveness of the disease. Likewise, SSM is partially defined by a very high serum tryptase level exceeding 200 ng/mL, and in many of these cases, progression does not occur for many years.[12,51,52,58–60,127,130] Contrasting the smoldering state, most patients with typical ISM have lower serum tryptase levels, although enzyme levels can vary widely among patients according to the MC burden.[12,51,111,127,130] Patients with ASM and MCL may exhibit serum tryptase levels in the several-hundred range to over 1000 ng/mL.[76,127,130] In many of these patients, serum basal tryptase levels increase rapidly over time (in contrast to ISM and SSM). Although discordances can exist between the serum tryptase level and the degree of MC infiltration of the marrow and other organs, it is the most useful and widely available biomarker that can be used to assess changes in the MC burden in response to cytoreductive therapy.[100,111]

Clinical Manifestations

Organomegaly

Splenomegaly and hepatomegaly, without associated organ damage, have traditionally been referred to as "B" findings and are one of the defining features of SSM.[12,51,58–60] Similarly, SM-related substantial (palpable, >2 cm) lymphadenopathy has been included in the category of "B" findings. Organomegaly by itself does not indicate inexorable progression to advSM or organ damage. However, even in the absence of organ damage, symptomatic splenomegaly may warrant therapeutic intervention similar to patients with myelofibrosis or other hematologic neoplasms.

Nonhematologic Organ Damage

The challenge of defining response parameters related to hepatic function is several-fold. First, for patients with SM with associated myeloid neoplasm, it is unclear whether liver dysfunction is related to the SM or the accompanying myeloid disease.[136] Concomitant diseases such as MPN or MDS/MPN such as CMML, CEL, or AML may (also) involve the liver and result in a hepatitis-like syndrome or obstructive liver disease. It is unknown what level of liver involvement by MC consistently results in liver dysfunction. Elevation of the alkaline phosphatase is the most common laboratory marker of clinically relevant liver involvement by SM.[137] Liver biopsy is sometimes performed and may help to assess the grade and extent of liver involvement by SM. Although liver biopsy may be informative, the potential information gleaned from the procedure must be weighed against potential complications such as bleeding, especially in the setting of severe thrombocytopenia and/or coagulopathy.

Hypoalbuminemia is an adverse prognostic factor for OS in SM[52]; it can reflect worsening synthetic function of the liver, and/or worsening nutritional status or even malabsorption because of GI infiltration by neoplastic MCs. The development of ascites in SM usually reflects aggressive liver disease and may be accompanied not only by hepatomegaly but also by abnormal liver function tests (e.g., elevated alkaline phosphatase as above) and/or portal hypertension.[12,51] More uncommonly, ascites may develop without evidence of liver disease, or in conjunction with massive abdominal lymphadenopathy. Similar to ascites, pleural effusions may develop in advSM, although it is an uncommon event. Every attempt should be made to establish that the ascites or pleural effusion is related to SM and/or the associated myeloid neoplasm, including evaluation of MC content.[136] Other causes of ascites or effusion should be excluded including infection, heart failure, and drugs such as dasatinib or avapritinib, that are used to treat advSM.[138,139]

Hematologic Organ Involvement

The etiology of cytopenias in advSM includes compromise of normal marrow reserve by infiltration with neoplastic MCs (often seen in ASM and MCL), ineffective hematopoiesis in the context of SM with an associated myeloid neoplasm, hypersplenism, and other causes such as recent myelosuppressive therapy or GI bleeding.[136] The coexistence of another myeloid neoplasm (AHN) often makes it difficult to ascertain the specific cause of the low blood counts. This distinction is not relevant to ISM, where the relatively lower MC burden is not expected to contribute to the development of cytopenias.

Molecular Features of Systemic Mastocytosis

Following the discovery of the somatic *KIT* D816V mutation in MC neoplasms in the mid-1990s,[140] it has become evident that this molecular abnormality is found in approximately 80% to greater than 90% of SM patients depending on the sensitivity of the assay and the patient population examined. *KIT* D816V has been detected throughout the hematopoietic hierarchy of SM patients, from hematopoietic stem cells to more lineage-restricted, MC-committed progenitors.[141] *KIT* D816V serves as a minor diagnostic criterion for the disease, and is considered a major driver of SM pathogenesis.[12,40,51] However, although promoting differentiation of progenitor cells into MCs, *KIT* D816V is neither a proliferation-promoting nor an oncogenesis-driving oncoprotein, and therefore, other additional mutations are required to fully transform a premalignant neoplastic state such as ISM to advSM. Rare codon 816 variants such as D816A/F/H/I/N/T/Y have also been described and are considered functionally equivalent to D816V.[40,100,142] Mutations affecting codon 816 are located in exon 17 and affect the second TK domain (TK2) that contains the phosphotransferase site and activation loop of KIT. Other mutations that have been identified in exon 17, for example in cases of ASM and MC sarcoma, include D820G and N822K.[143,144] *KIT* mutations in exons 8 to 9 of the extracellular region (del419, S451C, ITD 502–503) and the TM region (exon 10; e.g., F522C), and JM domain (exon 11; e.g., V560G/I) comprise some of the additional rare mutations in *KIT* that have been observed (Fig. 75.6).[40] With a few exceptions (e.g., V559I), mutations affecting these domains are more likely to exhibit sensitivity to imatinib, whereas codon 816 variants are imatinib-resistant.[145,146] Contrary to other SM subtypes, the frequency of *KIT* D816V is more variable in MCL; *KIT* D816V was found in 13 of 28 (46%) evaluable patients in one study, but was found in 24/28 (86%) MCL patients in another series.[75,76] MCL patients may exhibit other variants within *KIT*, or sequencing of the entire *KIT* gene may reveal no mutations. Increasingly sensitive assays

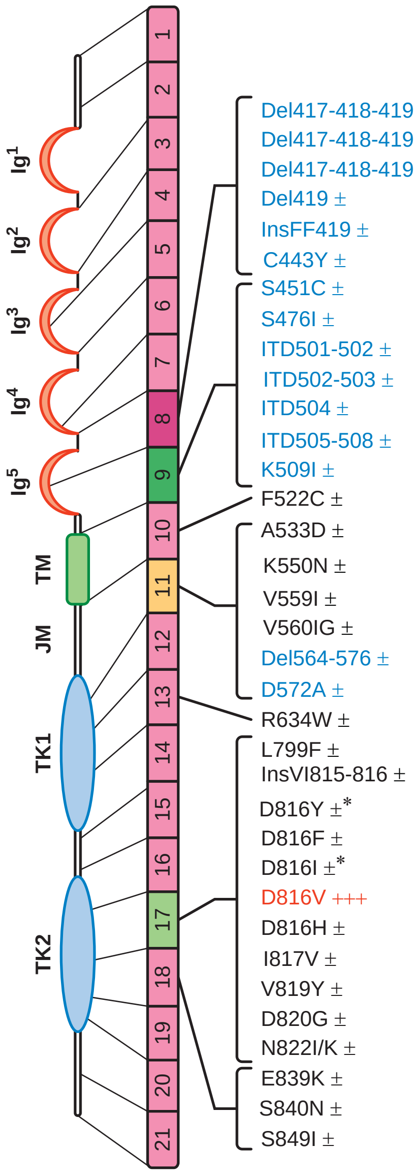

Figure 75.6 STRUCTURE OF THE *KIT* GENE AND MUTATIONS IN MASTOCYTOSIS. Representation of the structure of *KIT*, illustrating the localization of the more frequently observed mutations in the *KIT* sequence in pediatric and adult patients with mastocytosis. The receptor is presented under its monomeric form, whereas its WT counterpart dimerizes upon ligation with SCF before being activated in normal cells. In children, the *KIT* D816V PTD mutant *(in red)* is found in nearly 30% of the patients, whereas the ECD mutants *(in blue)* are found in nearly 40% of the affected children, the most frequent being the deletion 419. In adults, depending on the category of mastocytosis, the *KIT* D816V mutant *(in red)* is found in at least 80% of all patients. The complete list of *KIT* mutants retrieved in the literature for mastocytosis is depicted here. In children, the structure of *KIT* is found WT in ~25% of the patients analyzed, whereas in adults, *KIT* is found WT in <20% of all patients analyzed so far. Some of the mutations are found only in a very few number of patients. The symbols indicate the following: ±, mutation found in <10% of the pediatric or adult patients; +, mutations found in 1% to 5% of pediatric patients; ++, mutation found in 5% to 20% of pediatric patients; +++, mutation found in ~30% of pediatric patients and in >80% of all adult patients. *Mutation also found in children at low frequency. *Del*, Deletion; *ECD*, extracellular domain; *Ig*, immunoglobulin; *Ins*, insertion; *ITD*, internal tandem duplication; *JM*, juxtamembrane domain; *KI*, kinase insert; *PTD*, phosphotransferase domain; *TK*, tyrosine kinase; *TM*, transmembrane domain. *(From Arock M, Sotlar K, Akin C, et al. KIT mutation analysis in mast cell neoplasms: recommendations of the European Competence Network on Mastocytosis. Leukemia. 2015;29:1223,; Yarden Y, Kuang WJ, Yang-Feng T, et al. Human proto-oncogene c-kit: a new cell surface receptor tyrosine kinase for an unidentified ligand. EMBO J. 1987;6:3341.)*

(e.g., sensitivity of 0.01% to 0.1%), such as droplet digital PCR or allele-specific quantitative PCR for *KIT* D816V, are now available and can detect the mutation in the peripheral blood of almost all adult patients with SM.[147] Where available, it has been recommended that such sensitive assays be used as a valuable screening test for patients with suspected SM.[110,148] However, a low MC burden or the presence of other rare *KIT* or non-*KIT* mutations could lead to negative results; therefore a full workup with BM biopsy is warranted in typical cases where clinical symptoms and findings are highly suggestive of the presence of SM.

In a large cohort of pediatric mastocytosis patients, 36% exhibited *KIT* D816V mutations, and three (6%) patients had other codon 816 mutations (D816Y [$n = 2$] and D816I [$n = 1$]).[149] Another 44% demonstrated *KIT* mutations outside exon 17, with half of these being located in exons 8 and 9 (D417-418, D419Y, C443Y, S476I, ITD502-503, K509I) and exon 11 (D572A).[149] A retrospective systematic review of 1747 pediatric SM patients identified *KIT* D816V in 34% of 215 sequenced cases.[150]

SM-AHN cases commonly harbor molecular abnormalities related to the myeloid disease component in addition to *KIT* D816V. For example, *JAK2* V617F has been found in SM with myelofibrosis[151]; *BCR::ABL1* in rare cases of concurrent SM-CML[152,153]; and in SM-AML, the t(8;21)(q22;q22) *RUNX1::RUNX1T1* rearrangement is a well-known association.[154–156] In cases of *KIT* D816V-positive SM, several reports have detailed the coexistence of additional myeloid neoplasm-related mutations, which are implicated in differentiation, epigenetic regulation, and control of the splicing machinery.[157–163] Molecular profiling of myeloid progenitor cells from SM-AHN patients using logical hierarchy analysis showed that somatic mutations in *TET2*, *SRSF2*, and *ASXL1* often precede *KIT* D816V.[164] The general themes that have emerged from multiple genetic studies are the following: (1) ISM tends to be more a pure *KIT* D816V-driven disease with absence of, or low frequency of, additional (known) molecular abnormalities; (2) *KIT* D816V restricted to the MC lineage is observed in the majority of ISM patients; however, multilineage representation of *KIT* D816V is associated with progressive ISM, SSM, or AdvSM; and (3) the presence of a multi-mutated molecular profile is usually associated with more advanced disease subtypes, particularly SM-AHN.[100,157–165] *TET2*, *SRSF2*, and *ASXL1* are the most common of the myeloid neoplasm-associated mutated genes (~20% to 35% of patients), but mutations in *DNMT3A*, *CBL*, *JAK2*, *K/NRAS*, *UA2F1*, *ZRSR2 EZH2*, *RUNX1*, *ETV6*, and *SETBP1* have also been identified.[157–165] The prognostic impact of some of these mutations is discussed below (see Survival and Prognostic Factors). Mutations in the ethanolamine kinase gene *ETNK1* were found to be enriched in SM patients with eosinophilia, but are commonly present with *KIT* D816V or other myeloid disease-associated mutations.[166] In addition, *ETNK1* mutations have been identified in ~9% of patients with atypical CML and in <5% of patients with CMML.[167]

KIT D816V has been demonstrated in both MCs and the AHN component (e.g., monocytes in CMML) by laser cell microdissection;[73] *TET2* and *KIT* D816V have been found together in flow-sorted MCs;[159] the *SRSF2* P95 hotspot mutation has been uncovered in both MCs and monocytes from a case of SM-AHN;[162] and finally, t(8;21) has been identified by fluorescence in situ hybridization (FISH) in the BM MCs and the leukemic clone of a patient with SM and AML.[154]

In 2003 the *FIP1L1::PDGFRA* fusion oncogene was identified in patients with a diagnosis of idiopathic hypereosinophilic syndrome.[168] This molecular abnormality is not visible by standard chromosome analysis and its detection requires either use of reverse-transcriptase polymerase chain reaction or, more commonly, FISH (see Chapter 74). Because this genetic lesion results from an interstitial 800-kb deletion on chromosome 4q12, which removes a segment of DNA involving the *CHIC2* gene, the diagnostic test is referred to as "FISH for the *CHIC2* deletion."[169] Patients with *FIP1L1::PDGFRA*-associated eosinophilia present with features of a MPN: splenomegaly, a hypercellular BM, and clinicopathologic characteristics that overlap with SM, including increased numbers of abnormal-appearing BM MCs, marrow fibrosis, and elevated serum tryptase levels. Although *FIP1L1::PDGFRA*-positive myeloid neoplasms may exhibit increased numbers of BM MCs, they usually form interstitial or loose clusters,[169] and the WHO does not consider this disease entity a subtype of SM.[12,51] However, in a smaller subset of patients, criteria for SM may be fulfilled even if a *KIT* mutation is not detected. Notably, in almost all cases with *FIP1L1::PDGFRA*-positive myeloid neoplasms, including those who have SM-CEL, MCs do not exhibit *KIT* D816V, even if they express CD25.[170] Although the *FIP1L1:PDGFRA* genetic abnormality was once considered mutually exclusive of *KIT* D816V, rare cases with both mutations have now been reported, including their coexistence in tryptase-positive microdissected MCs.[171]

TABLE 75.9 **Clinicopathologic Features of Eosinophilia-Associated *FIP1L1::PDGFRA*–Rearranged Myeloid Neoplasms Versus *KIT* D816V-Positive Systemic Mastocytosis**

Features	*FIP1L1::PDGFRA*–Rearranged	*KIT* D816V–Positive
Gender	Overwhelmingly male	Less gender skewing
Bone marrow mast cell aggregates	Loose clusters/interstitial	Dense aggregates
AEC/tryptase ratio	>100	≤100
Treatment	Imatinib sensitive	Imatinib-resistant; second-generation TKIs (e.g., midostaurin)
Symptom profile	Cardiac/pulmonary	Gastrointestinal/urticaria pigmentosa/anaphylaxis
Vitamin B_{12} level	Elevated	Often normal

AEC, Absolute eosinophil count; *TKI*, tyrosine kinase inhibitor.
Modified from Maric I, Robyn J, Metcalfe DD, et al. KIT D816V-associated systemic mastocytosis with eosinophilia and FIP1L1/PDGFRA-associated chronic eosinophilic leukemia are distinct entities. *J Allergy Clin Immunol.* 2007;120(3):680–687.

Investigators identified a set of clinical and laboratory features that could reliably distinguish patients with *KIT* D816V-positive SM with eosinophilia from individuals with the *FIP1L1::PDGFRA*-positive myeloid neoplasms with eosinophilia (Table 75.9).[170] These criteria may be particularly useful when molecular testing is not readily available. In the D816V *KIT*-positive group, GI symptoms, urticaria pigmentosa, thrombocytosis, median serum tryptase values, and the presence of dense MC aggregates in the BM were statistically significantly increased or more frequently represented compared with patients with the *FIP1L1::PDGFRA* gene fusion. Conversely, male sex, cardiac and pulmonary symptoms, median peak absolute eosinophil count, the eosinophil to tryptase ratio, and elevated serum B_{12} levels were higher or more common in the group with *FIP1L1::PDGFRA*.[170] A scoring system incorporating these clinical and laboratory parameters could reliably predict whether patients with peripheral eosinophilia and increased marrow MC burden carried the *FIP1L1::PDGFRA* gene fusion or the *KIT* D816V mutation, which is important for guiding targeted therapy options.[170] Treatment of *FIP1L1::PDGFRA*-positive myeloid neoplasms associated with eosinophilia is discussed in Chapter 74.

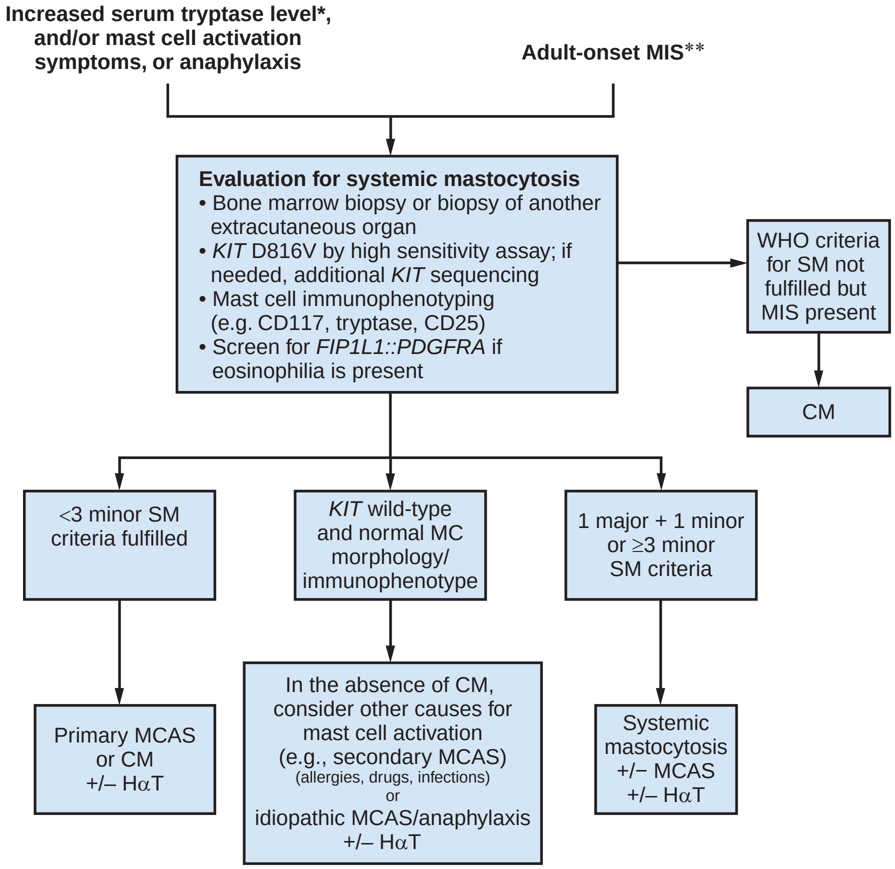
Additional Diagnostic Studies

In all patients with symptomatic SM, a thorough work-up for allergies, including total and specific IgE levels and HαT (tryptase gene copy number),[94–96] should be performed. Biochemical studies to evaluate for MC activation/mediator release include 24-hour urine evaluation of *N*-methylhistamine, prostaglandin D2, or 11-β-prostaglandin F2.[84] Bleeding diatheses have been reported in patients with MCAS or SM, and increased heparin levels can be found in patients with SM or MC activation.[172] Dual energy X-ray absorptiometry (DEXA) scans should be undertaken to screen for osteoporosis, and plain X-ray films (e.g., metastatic skeletal survey) are used to detect osteolytic lesions and/or pathologic fractures.[56] MC-related GI symptoms such as diarrhea and signs of malabsorption (e.g., hypoalbuminemia and weight loss) can be evaluated with endoscopy/colonoscopy with biopsy using appropriate immunohistochemical stains (e.g., CD117, tryptase, CD25, and CD3 as a control T-cell marker) to highlight abnormal MCs.[173] Ultrasonography, CT, and/or MRI of the abdomen/pelvis (with or without volumetric imaging) are utilized to determine the presence and extent of B and C findings such as hepato/splenomegaly, portal hypertension, ascites, and lymphadenopathy.

Diagnostic Decision Making

In patients presenting with MC activation symptoms or anaphylaxis without signs of cutaneous involvement, and a normal or elevated serum tryptase level, the diagnostic workup is centered on establishing whether WHO diagnostic criteria for SM are met (Fig. 75.7).[12,51] If these criteria are not satisfied, a workup is performed to rule out or diagnose MCAS or HαT, and to document (other) primary and secondary causes of MC expansion or MC activation.[110,148,174]

In adult patients with cutaneous MC lesions, the large majority of such patients will ultimately be found to have SM according to WHO diagnostic criteria. A BM biopsy is generally recommended in these patients to establish a diagnosis of SM (see Fig. 75.7). In patients with modest elevations of the serum tryptase level, mild or no symptomology, nor evidence of blood count abnormalities or other signs of organ damage, diagnostic testing may not elicit short-term changes in management even if SM is found. However, given the differences in OS between adult CM and SM, and the fact that only those with SM develop severe bone disease (osteoporosis) requiring therapy, staging investigations should be extended in SM. BM analysis can be very helpful as an initial “forensic” assessment of these potential disease trajectories.[110,148,174,175] Children with skin lesions rarely have systemic disease. Therefore, a BM biopsy is generally not recommended in children unless the serum tryptase level is unusually high or progressively increasing, or organomegaly and/or blood count abnormalities emerge.



Increased serum tryptase level*, and/or mast cell activation symptoms, or anaphylaxis
Adult-onset MIS**
Evaluation for systemic mastocytosis
• Bone marrow biopsy or biopsy of another extracutaneous organ
• *KIT* D816V by high sensitivity assay; if needed, additional *KIT* sequencing
• Mast cell immunophenotyping (e.g. CD117, tryptase, CD25)
• Screen for *FIP1L1::PDGFRA* if eosinophilia is present
WHO criteria for SM not fulfilled but MIS present
CM
<3 minor SM criteria fulfilled
KIT wild-type and normal MC morphology/ immunophenotype
1 major + 1 minor or ≥3 minor SM criteria
Primary MCAS or CM +/– HαT
In the absence of CM, consider other causes for mast cell activation (e.g., secondary MCAS) (allergies, drugs, infections) or idiopathic MCAS/anaphylaxis +/– HαT
Systemic mastocytosis +/− MCAS +/– HαT

Figure 75.7 DIAGNOSTIC DECISION PATHWAYS FOR PATIENTS WITH MAST CELL ACTIVATION SYMPTOMS (MCAS) OR ADULT-ONSET MASTOCYTOSIS IN THE SKIN (MIS). For patients with mast cell activation symptoms or anaphylaxis (and/or increased serum tryptase level), or adult-onset MIS, screening to assess whether the diagnostic criteria for SM are met should be the first diagnostic checkpoint. For patients not meeting criteria for SM, evaluation for MCAS (primary vs. secondary vs. idiopathic) and idiopathic anaphylaxis is the next phase of evaluation. Patients with MIS for whom no signs of SM can be found may be categorized as cutaneous mastocytosis. Hereditary alpha-tryptasemia is also on the differential diagnosis of individuals with an elevated basal serum tryptase level and/or mast cell activation symptoms/anaphylaxis, and its prevalence is enriched in patients with systemic mastocytosis and severe idiopathic anaphylaxis. *The serum tryptase level may be below the 20 ng/mL threshold, or only transiently elevated. **Although an evaluation for systemic mastocytosis is generally recommended in adults with MIS with no blood count abnormalities or organ dysfunction, and a normal or mildly increased serum tryptase level, the value of performing a bone marrow biopsy should be discussed with the patient. *CM*, Cutaneous mastocytosis; *HαT*, Hereditary alpha-tryptasemia; *MC*, Mast cell; *MCAS*, mast cell activation syndrome; *MIS*, mastocytosis in the skin; *PDGFRA*, platelet-derived growth factor receptor A; *SM*, systemic mastocytosis; *WHO*, World Health Organization. *(Adapted from Pardanani A. How I treat patients with indolent and smoldering mastocytosis (rare conditions but difficult to manage). Blood. 2013;121:3085; Valent P, Akin C, Arock M, et al. Definitions, criteria and global classification of mast cell disorders with special reference to mast cell activation syndromes: a consensus protocol. Int Arch Allergy Immunol. 2012;157:215.)*

Survival and Prognostic Factors

In a Mayo series of 342 patients with SM (46% ISM, 12% ASM, 40% SM-AHN, 1% MCL), life expectancy in ISM was similar to age- and sex-matched normal controls.[52] By contrast, median OS (and leukemia-free survival) was inferior in patients with more advanced forms of SM. For example, the median OS was 41 months and 24 months, respectively for ASM ($n = 41$ patients) and SM-AHN ($n = 138$ patients), and only 2 months for MCL ($n = 4$) patients.[52] In a multivariate analysis, independent adverse prognostic factors included advanced age, weight loss, anemia, thrombocytopenia, hypoalbuminemia, and excess BM blasts.[52] In addition to an increased percentage of MCs on marrow aspirate smears, Spanish investigators found that multilineage involvement of the *KIT* D816V mutation in more than just MCs (e.g., other myeloid lineages, and sometimes lymphoid cells) is a poor prognostic factor and leads to an increased risk of progression to advSM.[61] Many of these patients may suffer from overt SSM. The identification of *KIT* D816V in BM mesenchymal stem cells from ISM patients was associated with more advanced disease features, a greater rate of disease progression, and a shorter progression-free survival (PFS).[176] In patients with SM, eosinophilia was associated with inferior outcomes in two studies of the ECNM registry, including a recent analysis of a large number of SM patients,[177,178] whereas another series found that eosinophilia was prognostically neutral.[65] SM patients with eosinophilia tend to suffer from SSM, ASM, or MCL, but even in ISM, eosinophilia may be detected.

Cytogenetic/Molecular Determinants of Prognosis and the Evolution of Prognostic Scoring Systems

In SM-AHN patients, the SM subtype wherein cytogenetic abnormalities are almost exclusively identified, progression to MCL or secondary AML, as well as shortened OS, were associated with monosomies or a complex karyotype, and were independent of mutational status.[179] However, there are also data to suggest that among SM-AHN patients, karyotype did not carry independent prognostic value in a multivariate analysis, in contrast to adverse mutations, anemia, and thrombocytopenia.[180]

An initial analysis of the molecular profile of SM patients found that the presence of one or more mutations in addition to *KIT* D816V was associated with inferior OS.[160] A separate analysis found that mutation of *ASXL1* had a significant negative impact on OS among a cohort of 62 patients with SM-AHN.[161] Inferior survival has also been observed in SM patients based on the presence of combined *TET2/DNMT3A/ASXL1* mutations independent of *KIT* and sole *TET2* mutations.[158] In a series of 70 multi-mutated advSM patients, OS was adversely influenced by the number of mutated genes in the *SRSF2/ASXL1/RUNX1* (S/A/R) gene panel.[181] In an independent series of 19 advSM patients, non-*KIT* mutations were frequent (79%), particularly in *TET2*, *ASXL1*, and *CBL*.[182] Presence of *ASXL1* and/or *CBL* mutations or occurrence of ≥3 non-*KIT* mutations was independently associated with significantly inferior OS, but not leukemia-free survival. A more recent study found that the presence of ≥1 multilineage mutation in the *S/A/R* gene panel and/or the *EZH2* gene was the sole independent predictor for PFS and OS.[183]

These correlative clinical and genetic studies provided the foundation for the development of clinical-molecular prognostic scoring systems that continue to undergo evolution and further refinement (reviewed in 100). An initial prognostic scoring system employed clinical features (elevated alkaline phosphatase and increased spleen volume) and the presence of additional mutations besides *KIT* D816V.[137] The International Prognostic Scoring System for Mastocytosis (IPSM) uses clinical and laboratory features to further stratify outcomes of patients comprising cohorts of both non-advanced and advSM patients.[53] Other prognostic models are molecularly-anchored; these include the Spanish Network on Mastocytosis (REMA) prognostic scoring system for ISM patients,[184] and their Global Prognostic Score for Mastocytosis (GPSM), which is currently undergoing validation.[185] Additional hybrid clinical-molecular prognostic scoring systems include the Mutation-Adjusted Risk Score (MARS) for advSM patients,[186] as well as the Mayo Alliance Prognostic Scoring System (MAPS), which also includes a separate cohort analysis based on clinical and laboratory information only, excluding data regarding WHO subgroup classification and genetic profile.[187,188] The clinical, laboratory, and molecular variables that comprise these prognostic scoring systems are shown in Table 75.10.

TABLE 75.10 Prognostic Scoring Systems in Systemic Mastocytosis

Parameters		REMA (for ISM)			IPSM			GPSM	
		OS	PFS	MAPS	Non-Adv	Adv	MARS	OS	PFS

Figure 75.8 TREATMENT OPTIONS FOR ADVANCED SYSTEMIC MASTOCYTOSIS VARIANTS. Treatment options are listed based on the subvariant of advanced SM which comprises aggressive systemic mastocytosis, systemic mastocytosis with an associated hematologic neoplasm, and mast cell leukemia. For SM-AHN, the initial decision is whether treatment is more immediately necessary for the SM or AHN component. *ASM*, Aggressive systemic mastocytosis; *HSCT*, hematopoietic stem cell transplantation; *MCL*, mast cell leukemia; *SM*, systemic mastocytosis; *SM-AHN*, systemic mastocytosis with an associated hematologic neoplasm.

TREATMENT

Therapy of mastocytosis centers on addressing symptoms related to MC activation (in all categories), and using cytoreductive agents to reverse organ damage caused by neoplastic MC infiltrates in advSM. In the United States, the National Comprehensive Cancer Network (NCCN) has produced guidelines which continuously update algorithms for the diagnosis, prognostication, and treatment of the spectrum of SM subtypes.[148] Fig. 75.8 illustrates the treatment options for the advSM variants ASM, SM-AHN, and MCL. For SM-AHN patients, the first major therapeutic consideration is whether the SM or AHN component requires more immediate therapy. The role and timing and allogeneic hematopoietic stem cell transplantation (HSCT) is still being defined, especially in the age of KIT-targeting agents.

Mast Cell Activation Symptoms/Anaphylaxis

All adult mastocytosis patients, regardless of prior anaphylactic events, should carry two doses of an adrenaline autoinjector (and should be instructed in its safe use, e.g., by an allergist) to treat potential future episodes of anaphylaxis. In addition, emergency medicines such as diphenhydramine or oral prednisolone should be considered, although their utility for mitigating acute symptoms is less well-established.[11,13,174] Because anaphylaxis can also be a feature of MCAS, these patients are candidates for similar therapy even if no overt SM was diagnosed.[84–87,92] An additional trigger of severe symptoms may be HαT. Therefore, HαT should also be confirmed or excluded in these patients, regardless of the confirmed presence of an IgE-dependent allergy.[94–96] The treatment of choice for life-threatening Hymenoptera allergy/anaphylaxis is venom immunotherapy that should be undertaken with caution using a multidisciplinary approach led by allergists.[92,174,189–192] Similarly, perioperative management of anesthetics, which can precipitate immediate and delayed MC activation, requires consultation with the surgical, anesthesiology, and allergy teams to minimize the occurrence and severity of anaphylaxis. General guidelines regarding anesthesia and analgesic management in patients with mastocytosis undergoing procedures or surgery, as well as management of pregnancy, have been published.[148,191,193–206]

The treatment of MC activation symptoms follows a stepwise approach using antimediator drugs and other supportive care measures.[11,13,70,174] These medications include H1-histamine blockers for flushing and pruritis, and H2-histamine blockers for SM-related GI symptomatology such as diarrhea, abdominal discomfort/cramping, and peptic ulcer disease. Leukotriene antagonists such as Montelukast are commonly added to H1-histamine blockers for persistent flushing and pruritis. In rare cases, aspirin can be an alternative therapy for refractory flushing, but needs to be used with caution because of its ability to precipitate MC activation, bleeding tendency, and GI tract ulcerative disease. In general, however, aspirin is not recommended for use in SM. Although the MC stabilizer sodium cromoglycate (Gastrocrom) is geared to persistent GI symptoms such as diarrhea, proton pump inhibitors may be specifically useful for patients with refractory GERD/peptic ulcer disease. Alternative treatments that have been used for refractory mediator symptoms include the off-label antihistamine/MC stabilizer ketotifen,[207] and the anti-IgE antibody omalizumab[208–212] has also been used for anaphylaxis, as well as asthma. Although bisphosphonates (alendronate 70 mg q week; risedronate 35 mg q week; pamidronic acid 90 mg intravenously (IV) q 4 weeks; and zoledronic acid 4 mg IV q 4 weeks) are recommended for bony disease, reports of their use in SM primarily consist of single cases or small cases series.[56,70,148,174,213–217] A generally accepted rule is to start with a bisphosphonate when the T-score drops to below −2.[84] IFN-α has been employed with bisphosphonates and/or as single agent therapy, especially for patients with refractory bony pain and/or MC-related osteoporosis and pathologic fractures.[218,219] Anti-RANKL monoclonal antibody therapy (e.g., denosumab) is generally used as second-line therapy for patients with bone pain not responding to bisphosphonates or for patients who are not candidates for bisphosphonates because of renal insufficiency.[148,220] Concerns regarding the cosmetic appearance of cutaneous lesions or skin-related mediator symptoms refractory to the aforementioned therapies can be helped for a limited period of time with phototherapy (UVA$_1$, narrow-band UVB, and UVA plus psoralen). In addition, occlusion dressings embedded with topical steroids with or without phototherapy, and both topical and oral forms of sodium cromoglycate, have been used with some benefit.[221]

Cytoreductive Agents

IFN-α and cladribine (2-chlorodeoxyadenosine) have typically been used for patients with progressive SSM and for cytoreduction in advSM patients (ASM, MCL, and SM-AHN) to reduce or reverse organ damage. In most instances, cladribine is favored over IFN-α to induce debulking of neoplastic MCs in advSM patients.[72,100,148,174] The use of both drugs is recommended to treat patients with less rapidly progressive disease (PD). In addition, cladribine and IFN-α are sometimes used to control mediator symptoms, especially when these symptoms are refractory to conventional anti-mediator-type drugs. In addition, low-dose IFN-α has been suggested for ISM patients with drug-resistant osteoporosis.[218,219] Otherwise, however, these agents are not recommended for use in ISM or SSM. In patients with rapidly progressive ASM or MCL, more intensive therapy is usually recommended, whereas cladribine alone or IFN-α alone are insufficient to control rapid disease expansion or transformation in SM.

Interferon-α

IFN-α has been used as monotherapy or in combination with corticosteroids, mostly in patients with ASM with slow progression or mono-organ involvement. For example, the drug works effectively in patients with ASM with liver involvement and ascites. Prednisone or prednisolone 0.5 to 1 mg/kg is initiated with IFN-α (or as a lead-in dose for several days prior) in order to improve its efficacy and tolerability, and tapered over 2 to 3 months if feasible.[70,72,148] In some patients with severe and persistent mediator symptoms or organ damage that is particularly responsive to corticosteroids, a longer-term maintenance dose (e.g., ≤10 mg daily) may be required. IFN-α dosing has been variable between studies and an optimal dose has not been identified. Starting doses have ranged from 1 million units (MU)/day to 3 MU three times weekly, with median total weekly maintenance doses in the range of 15 to 30 MU.[70,72,148] Because of the (low) risk of anaphylactic reactions, consideration should be given to hospitalization of patients during the first days of treatment, if possible.

In the Mayo experience with IFN-α (with or without prednisone), 21 of 40 evaluable patients responded (53%); response rates by subgroup were: six of 10 ISM, six of 10 ASM, and nine of 20 SM-AHN.[70,222] The 21 responses consisted of one complete remission (CR), six major responses (MRs), and 14 partial responses (PRs). The median duration of response (DOR) was 12 months (range, 1 to 67) with no statistical difference between responders and nonresponders regarding use of prednisone or the median weekly dose of IFN-α. However, the absence of mediator-related symptoms was associated with a significantly lower response rate.

In the French experience with 20 SM patients (four ISM and 16 ASM), IFN-α-2b was initiated at 1 MU daily and progressively increased as tolerated up to 5 MU/m^2 daily.[223] Among the 13 patients treated for at least 6 months (mean daily dose: 3.2 MU daily), all had partial or complete resolution of systemic or cutaneous disease manifestations and/or MC mediator levels, but no significant reduction in BM MC burden. The lack of a substantive effect on tumor load and rapid relapse in four responding patients after drug withdrawal suggests that IFN-α exerts a cytostatic effect on MCs.

Responses to IFN-α primarily include amelioration of MC mediator symptoms and associated laboratory markers of MC activation such as levels of histamine or its metabolites. Single cases and small case series, in addition to the aggregate data from the aforementioned larger trials, indicate variable potential to ameliorate skin lesions, osteoporosis, and C findings such as cytopenias, hepato/splenomegaly with liver dysfunction and/or ascites, and weight loss.[218,219,222–227] Toxicities associated with IFN-α such as flu-like symptoms, myelosuppression, transaminitis, hypothyroidism, depression, and bone pain are not uncommon, and result in a moderate proportion of patients requiring dose-reduction or drug discontinuation.

Cladribine

Cladribine has been used off-label across a spectrum of SM subtypes. Cladribine has received orphan designation (not marketing authorization) for the treatment of SM in Europe. Following an initial report indicating that cladribine could elicit improvement of mediator symptoms, urticaria pigmentosa lesions, and reduction of MC burden and the serum tryptase level,[228] Kluin-Nelemans and colleagues published a series of 10 patients, including 3 with ISM, 1 SSM, 3 SM-AHN, and 3 ASM.[229] Cladribine was administered for 5 days every 4 to 8 weeks at a dose of 0.10 to 0.13 mg/kg over 2 hours IV. Among 9 evaluable patients (1 discontinued because of toxicoderma), the drug elicited improvement in symptoms, and a decrease (often rapid) in urticaria pigmentosa lesions, MC burden, serum tryptase levels, and urine metabolites of MC activation.

In the Mayo Clinic experience, cladribine was administered for 5 days at a dose of 5 mg/m^2/day (or 0.13 to 0.17 mg/kg/day) IV.[70,222] A median of 3 cycles (range, 1 to 9) was administered. The overall response rate was 55% (12/22 patients) consisting of 1 CR, 7 MR, and 4 PR. Responses were observed in 5 of 9 ISM, 1 of 2 ASM, and 6 of 11 SM-AHN patients. Improvement in mediator symptoms, organomegaly, C-findings (e.g., ascites, anemia), and markers of MC burden and/or activation (e.g., serum tryptase level and MC-derived urine metabolites) were observed. The median response duration was 11 months, and inferior outcomes were predicted by leukocytosis, monocytosis, and circulating immature myeloid cells, the latter remaining significant in a multivariate analysis.

The long-term French experience with cladribine in both indolent ($n = 36$) and advanced ($n = 32$) SM patients have been published.[230] Cladribine was administered as an infusion or subcutaneously at a dose of 0.14 mg/kg, for 1 to 5 days, every 4 to 12 weeks. A median of 3.7 courses was administered (range, 1 to 9). The overall response rate was 72%, split between 92% and 50% for indolent and advanced disease, respectively. Among patients with advSM, the respective CR, MR, and PR rates were 0%, 37.5%, and 12.5%. Significant decrease in serum tryptase levels was only observed in ISM patients, and changes in BM MC burden were only evaluated in nine patients, precluding a substantive conclusion regarding this endpoint. Median durations of response were 3.71 (range, 0.1 to 8) and 2.47 (range, 0.5 to 8.6) years for indolent and advSM, respectively. Lymphopenia (82%), neutropenia (47%), and opportunistic infections (13%) were the most common grade 3/4 adverse events. Although cladribine has activity in selected patients with SM, its use in subjects with indolent disease (even those with refractory mediator symptoms) needs to be approached very cautiously because of the potential for substantial high-grade toxicities in these individuals who otherwise exhibit similar survival to age-matched controls.

Tyrosine Kinase Inhibitors

Dasatinib and Nilotinib

Multikinase inhibitors with activity against KIT have been evaluated in patients with advSM. Dasatinib is a dual SRC/ABL kinase inhibitor that is approved for front-line treatment of chronic myeloid leukemia. Despite dasatinib exhibiting nanomolar activity against KIT D816V in vitro,[231,232] a case series and a phase II trial of dasatinib (140 mg total daily dose) revealed limited activity in

SM.[138,233] In the phase II trial of 33 patients (ISM, $n = 18$; ASM, $n = 9$; SM-AHN), 11 (33%) responded.[138] Two complete responses were recorded in patients who were negative for the *KIT* D816V mutation, including a patient with *JAK2* V617F-positive SM-PMF and a patient with SM-CEL. The other 9 responses provided symptomatic benefit only, without clinically significant reductions in either BM MC burden or serum tryptase levels. The drug's short half-life may be one contributory reason for its lack of activity in SM patients. In fact, although dasatinib can block both MC growth and IgE-dependent MC activation in vitro, no reproducible effects are seen in SM patients in vivo.

Nilotinib was evaluated in an open-label trial of 61 patients with SM; among the cohort of 37 advSM patients, 8 (22%) exhibited objective responses with reductions in MC burden and/or serum tryptase level.[234] Taken together, these agents have shown low overall response rates in phase II trials and are no longer being pursued in advSM.

Imatinib

Imatinib is approved for ASM without the *KIT* D816V mutation or with unknown *KIT* mutational status. The clinical benefit of imatinib in SM is therefore limited given the high prevalence of the *KIT* D816V mutation, and the increasing sensitivity and widespread use of assays that can detect this molecular abnormality. Although imatinib lacks activity against KIT D816V in vitro and in vivo,[235–239] it has led to clinical benefit in patients with alternative *KIT* mutations or wild-type *KIT*. For example, imatinib has elicited excellent responses in cases of the WDSM variant with either the F522C TM *KIT* mutation[78] or wild-type *KIT*;[79] in a patient with familial SM carrying the germline *KIT* K509I mutation;[240] with deletion of codon 419 in exon 8 of *KIT* in pediatric CM;[241] and in a case of MCL with mutation in exon 9 (p.A502_Y503dup).[80] It is also noteworthy that long-term treatment with imatinib (400 mg/day) is associated with an almost complete MC deficiency, which may be of clinical relevance in reactive (nonclonal) MCAS and other MC-dependent diseases.

Masitinib

Masitinib (AB1010), is an inhibitor of Lyn, Fyn, PDGFR-α/β, and wild-type KIT.[242] After an initial study II trial in patients with ISM or CM with symptoms unresponsive to prior therapy,[243] masitinib was studied in a phase III, randomized, double-blind trial of 135 patients with ISM or SSM (108 subjects formally satisfied the WHO criteria for SM). Subjects were randomized to oral masitinib (6 mg/kg daily in two daily doses) or placebo.[244] The primary end-point of the study was based on a 75% or more improvement in one or more symptom categories: pruritis, flushing, depression, or fatigue. Of the patients taking masitinib, 18.7% achieved this endpoint compared to 7.4% of patients taking placebo. At week 24, there was an 18% decrease in the serum tryptase level in the masitinib arm versus an increase of 2.2% in the placebo arm ($P < .0001$). Also, urticaria pigmentosa lesions on masitinib therapy decreased by an average body surface area of 12.3% versus an increase of 15.9% for the placebo group. Masitinib-associated clinical benefits were generally sustained during a two-year extension period. Although treatment was generally well tolerated, there was an excess incidence of diarrhea, rash, and asthenia in 9%, 6%, and 4% of patients, respectively, in the masitinib group. In addition, 24% of patients in the masitinib arm discontinued therapy because of an adverse event, compared with 10% in the placebo arm. Masitinib has not received health regulatory approval for ISM or SSM.

Midostaurin

Midostaurin (*N*-benzoylstaurosporine; PKC412) is an inhibitor of multiple TKs including wild-type and D816V-mutated KIT, FLT3, PDGFR-α/β, FGFR1, and VEGFR2. In Ba/F3 cells transformed by *KIT* D816V, the IC_{50} of midostaurin was 30 to 40 nM compared with greater than 1 μM with imatinib.[236,237] A PR with midostaurin in a patient with MCL and an associated MDS/MPN,[237] and encouraging responses in a phase II trial of 26 patients with advSM[245] led to a global, multicenter, open-label trial of midostaurin (100 mg twice daily on 28-day continuous cycles) in patients with ASM, MCL, and SM-AHN.[246]

The trial employed a steering committee and central pathology review to adjudicate eligibility, response, and histopathology.[246] Among 89 evaluable patients, the ORR was 60%, of which 75% were major responders (MRs). Responses in organ damage (e.g., normalization of cytopenias/red blood cell or platelet transfusion dependence) and liver function abnormalities (hypoalbuminemia) were observed regardless of *KIT* D816V status, prior therapy, or the presence of an AHN. The median best reduction in serum tryptase level was −58%. In addition, the median change in BM MC burden was −59%, and 57% of patients had a ≥50% reduction in BM MCs. After a median follow-up of 26 months, the median duration of overall response (DOR) and median OS were 24.1 and 28.7 months, respectively. Median OS in responders was 44.4 months compared with 15.4 months in nonresponders. Of the 16 patients with MCL, 8 responded, including 7 MR (44%); among MCL patients, the median DOR was not reached, with three MRs ongoing at 49, 33, and 19 months at the time of data cut-off. The median OS was 9.4 months among all patients with MCL but was not reached among responding MCL patients. Symptoms and quality of life, measured by the Memorial Symptom Assessment Scale (MSAS) and Short-Form 12 (SF-12) survey, respectively, were significantly improved with midostaurin treatment. Improved symptoms and quality of life may relate to the ability of midostaurin to block IgE-dependent mediator release from MCs in vitro.[247] The drug was generally well tolerated with a manageable toxicity profile consisting mostly of GI side effects, including nausea and vomiting, primarily grade 1 to 2 in nature.

Among a cohort of 38 advSM patients treated with midostaurin, response rate and OS were significantly higher in patients with at least a 25% reduction in *KIT* D816V RNA-expressed allele burden (i.e., *KIT* responders) and in patients without *S/A/R* mutations.[248] In a multivariate analysis, *KIT* responder status was the strongest and only on-treatment variable associated with prolonged OS. Progression of midostaurin-treated patients to MCL or secondary AML was associated with ≥1 *S/A/R* mutations, an increase in the allele burden of preexisting mutations, or on-treatment development of new mutations in genes such as *K/NRAS*, *RUNX1*, *IDH2*, and *NPM1*.

Avapritinib

Avapritinib (BLU-285; Blueprint Medicines) is an oral type 1 multikinase inhibitor with highly selective and potent activity against *PDGFRA* A-loop mutants and *KIT* D816V ($IC_{50} = 0.27$ nM), which is 10-fold more potent than midostaurin.[249] A multicenter phase I trial accrued 69 patients into dose escalation ($n = 37$) and dose expansion ($n = 32$) cohorts, with the resulting recommended go-forward dose of 200 mg daily[139] currently being evaluated in an ongoing phase II study. Among the 53 patients evaluable using modified IWG-MRT-ECNM response criteria in the phase I trial,[139] the overall response rate was 75%; this comprised a 36% CR rate with full or partial hematologic recovery ([CR, 8%] + CR with partial hematologic recovery [CRh, 15%]), 34% PR, and 6% clinical improvement (CI).[139] Response rates by advSM subgroup were 100%, 76%, and 69% in patients with ASM, SM-AHN, and MCL, respectively. A >50% in BM MCs was observed in 92% of patients, and a >50% decrease in serum tryptase level was achieved in 99% of patients. Notably, *KIT* D816V became undetectable in 30% of patients using digital droplet PCR with a sensitivity of 0.17%. The most common adverse events (all grades/grade 3 to 4, %) were periorbital edema (69/2), anemia (55/30), diarrhea (45/1), nausea (44/3), thrombocytopenia (44/23), fatigue (41/9), and peripheral edema (40/0). Intracranial bleeding (ICB) occurred in 13% overall, and in 1% of patients without severe thrombocytopenia. A pre-specified interim analysis of the phase II PATHFINDER study evaluating 32 advSM patients demonstrated an ORR of 75% and similar safety profile with only 1 case of ICB due to implementation of mitigation procedures for thrombocytopenia.[250] Avapritinib was approved for patients with ASM, SM-AHN, and MCL in June of 2021. The recommended starting dose for patients with advSM is 200 mg daily. This drug is not recommended for the treatment of patients with platelet counts less than 50 × 10^9/L due to the higher risk of ICB in these patients.

Avapritinib is also being evaluated in patients with ISM; in stage 1 of a double-blind, placebo-controlled, randomized study, a 25 mg daily dose was chosen as the recommended dose for further evaluation in stage 2, the open-label portion of the trial.[251]

The oral type 2 switch control kinase inhibitor ripretinib (DCC-2618; Deciphera Pharmaceuticals) exhibits activity against multiple KIT and PDGFR-α mutants, with antineoplastic activity in preclinical models using *KIT* D816V-transfected MC lines (IC_{50} = 133 to 256 nM).[252] Enrollment of advSM patients in a phase II trial of ripretinib at a dose of 150 mg twice daily has been completed. Bezuclastinib (CGT9486) is an oral, highly selective TK inhibitor with potent activity against *KIT* D816V which is also commencing trials in both indolent and advSM.

Other Agents

Hydroxyurea has been used to control leukocytosis and splenomegaly in patients with a concurrent AHN such as MPN, CEL/HES, or MDS/MPN.[225] Multiagent, intensive chemotherapy is usually reserved for patients with MCL, especially for patients with kinetically active disease, but the results thus far have generally been disappointing.[253] Anthracycline plus cytarabine-based induction chemotherapy is the standard of care for patients with AML who are suitable for high-intensity therapy, including those in whom SM is also present. In such cases, treatment of the AML almost always takes priority, and the finding of the *KIT* D816V mutation may provide an opportunity to consider the addition of KIT inhibitors such as midostaurin to the induction, consolidation, and/or maintenance phases of treatment. However, the safety and efficacy of this approach has yet to be validated in the context of clinical trials. Several antibodies and antibody-drug conjugates have been considered for use in advSM. For example, the anti-CD30 antibody-drug conjugate brentuximab vedotin (BV) induces growth inhibition and apoptosis of $CD30^+$ MCs. However, a clinical trial evaluating BV did not demonstrate activity in advSM patients with $CD30^+$ MC.[107] Other agents that may be useful for the eradication of neoplastic MCs and possibly also neoplastic stem cells include anti-CD33, CD44, CD52, and CD123 antibody-drug immunoconjugates (or naked monoclonal antibodies).[254–257]

Allogeneic Hematopoietic Stem Cell Transplantation

Until recently, the role of HSCT in advSM remained poorly characterized, and only on a limited number of case reports and series had appeared. In a large, multicenter retrospective analysis, Ustun and colleagues evaluated the outcomes of 57 SM patients (SM-AHN, $n = 38$ [AML = 20]; ASM, $n = 7$; and MCL, $n = 12$) who underwent allogeneic HSCT.[258] Donor types consisted of HLA-matched identical ($n = 34$) and unrelated ($n = 17$) donors, umbilical cord blood ($n = 2$), and haploidentical ($n = 1$), and three unknown. Responses were observed in 70% of patients, including a 16% CR rate. The remaining 30% of responses were split between stable disease (21%) and primary refractory disease (9%). All 38 patients with SM-AHN achieved CR regarding the AHN component, but 10 subsequently relapsed with AHN, and half of these patients died.

The median OS for all patients at 3 years was 57%, consisting of 74% for patients with SM-AHN, and 43% and 17% for ASM and MCL patients, respectively.[258] The strongest risk factor for a poor OS was a diagnosis of MCL. In addition, inferior survival was observed in patients undergoing reduced-intensity versus fully myeloablative conditioning. However, patient age, donor age, donor type (sibling or unrelated donor), graft source (BM or peripheral HSCT, *KIT* mutation status, karyotype), and total-body irradiation used in myeloablative conditioning had no impact on overall or PFS. Treatment-related mortality at 6 months and 1 year was 11% and 20%, respectively, and was highest in MCL patients. Although a prospective trial is needed to better define the role of HSCT in advSM, these data suggest that transplantation can provide extended survival in selected patients, particularly for patients with SM-AHN. Consensus opinions have been developed for the use of HSCT in advSM,[259] but will continually evolve in the context of KIT-targeting drugs and combination therapies to address both the SM and AHN components.

Response Criteria for Advanced Systemic Mastocytosis

Response criteria for advSM were first published in 2003 and reiterated in a consensus conference report in 2007.[84] In this system, evaluation of clinical evidence of organ damage, or “C” findings, was the foundation for distinguishing levels of response. Changes in BM MC burden, serum tryptase level, and hepatosplenomegaly were additionally employed to subcategorize levels of MR. These original criteria or their modified version have been used to adjudicate responses in clinical trials of new agents.

Several shortcomings emerged regarding these SM response criteria. First, achievement of an “MR” is permitted in patients with baseline laboratory values just outside of the normal reference range. Second, responses in C-findings such as ascites, weight loss, and bone lesions are often difficult to quantify. Third, criteria for baseline red blood cell and platelet transfusion dependence were not codified. Lastly, the minimal DOR was not clearly defined, although a minimum response duration of 8 weeks has been incorporated ad hoc into many trials.

In 2013, the International Working Group for Myeloproliferative Neoplasms Research and Treatment (IWG-MRT) and the ECNM established revised response criteria for advSM that better characterize nonhematologic and hematologic organ damage findings, and lend more specificity and quantitation to evaluation of clinical and histopathologic improvement, which require 12-week duration.[136] IWG-MRT-ECNM response criteria, or modifications of these definitions are now being incorporated into clinical trials and are being used by regulatory health agencies such as the Food and Drug Administration and European Medicines Agency to evaluate new agents for approval.

FUTURE DIRECTIONS

Several clinical and translational initiatives are being pursued in MC disease and should reach fruition in the near future. In 2020, an AIM/ECNM (US/EU) Working Conference developed a proposal for revised diagnostic criteria and classification of MC disorders and is expected to achieve broad integration into international guidelines.[260] Efforts to combine data from the ECNM registry,[261] which has enlisted over 5000 patients, with the nascent efforts of AIM, will be a high priority. Updated criteria for MCASs[262,263] and guidelines for vaccination against COVID-19 in patients with MC disorders[264] have provided further clarity for these challenging clinical scenarios.

In conjunction with biopharma, research groups are also validating SM-specific patient-reported outcome tools to qualitatively and quantitatively measure patients’ symptom burden and quality of life in the context of drug development for indolent and advSM. Regulatory health agencies are increasingly focused on these patient-reported outcomes as endpoints in phase II trials as well as phase III placebo-controlled, double-blind, randomized trials.

Clinical trials are under development to investigate targets and pathways relevant to MC pathobiology. These include JAK inhibitors (e.g., ruxolitinib), inhibitors of BCL-2 (e.g., venetoclax), and agonist antibodies against inhibitory receptors such as siglec-8 in order to induce MC apoptosis. Major unmet needs include the development of combination therapies for SM-AHN using AHN-directed therapies plus KIT inhibition, or syncopated schedules of cladribine + KIT inhibitors in advSM patients with refractory disease or suboptimal responses with KIT inhibitor monotherapy.[100] Biologic correlates of therapeutic response such as minimal residual disease analysis using sensitive PCR assays to interrogate *KIT* mutant allele burden,[139] as well as circulating tumor DNA and cytokine profiling are now being incorporated into trials. Multi-omic analyses (e.g., genomic, transcriptomic, and proteomic profiling) of MCs and AHN populations and their progenitors using single cell assays will help further define the biologic heterogeneity of SM-AHN.

CHAPTER 76

CHRONIC LYMPHOCYTIC LEUKEMIA

Farrukh T. Awan and John C. Byrd

Over the past several years, major advances have been realized in terms of improved understanding of the pathophysiology and therapeutic options for chronic lymphocytic leukemia (CLL). The plethora of information about CLL has increased dramatically and made management of what was a relatively straightforward disease quite complex but more rewarding. This chapter provides a reference source focused on critical issues in routine clinical management of CLL.

EPIDEMIOLOGY

CLL is one of the most prevalent types of leukemia in the Western Hemisphere. Surveillance, Epidemiology, and End Results (SEER) estimates for 2021 indicate that approximately 21,250 patients (13,040 men and 8210 women) would be diagnosed in the United States and that 4320 patients would die from CLL. The median age at diagnosis for CLL was 70 years in 2020, and incidence increases proportionately by decade of life as shown in Fig. 76.1. This figure illustrates that CLL is a very uncommon diagnosis before 45 years of age and infrequent (33% of total patients diagnosed) in patients before 65 years of age. The age-adjusted incidence rate was 5 per 100,000 men and women per year; 0.6% of men and women born from 2015 to 2017 are expected to be diagnosed with CLL during their lifetime. The estimated time of survival after diagnosis at 5 years is 86.1%, which explains the estimated prevalence of 186,422 in 2017. Similar to other types of leukemia, the risk of dying from disease-specific causes increases proportionately with increasing age. Another analysis of the SEER database, comparing outcome of elderly patients with CLL with age- and sex-matched healthy control participants, demonstrated that CLL has the greatest impact on survival in the most elderly group of patients. However, recent therapeutic advances continue to result in significant improvement in outcomes across all age groups.

CLL is more common in men than women. Women diagnosed with CLL have 5- and 10-year overall survival (OS) rates that exceed those of men. CLL is most common in whites and decreases in frequency in a descending order among blacks, Hispanics, Native Americans and Native Alaskans, and Asians and Pacific Islanders. While adverse outcome based upon race has been reported, this has not been uniformly confirmed in other studies. The rarity of CLL among Asians and Pacific Islanders persists even in immigrants from these areas who have migrated to the Western Hemisphere. This implicates a possible genetic predisposition to the development of CLL. The relationship of environmental factors such as exposure to benzene, radon, and other chemicals to the development of CLL is suggestive but not clearly established. However, CLL is recognized as a service-connected illness among Vietnam War veterans who were exposed to Agent Orange. Occupational or environmental exposure to radiation does not clearly appear to predispose patients to a higher risk of developing CLL. For example, although the frequency of acute myeloid leukemia (AML), chronic myeloid leukemia (CML), and acute lymphoblastic leukemia (ALL) were increased among survivors of the atomic bomb at Hiroshima, an increase in CLL was not appreciated as reported by the Life Span Study (LSS) of survivors of that event. This could be secondary to a baseline low incidence of CLL in patients with Asian heritage. However, recent reports of Chernobyl disaster survivors and the international nuclear workers (INWORKS) study suggest an increased incidence of CLL along with a shorter survival. In addition, the International Lymphoma Epidemiology Consortium non-Hodgkin lymphoma Subtypes Project (InterLymph Study) identified multiple factors that were associated with the presence of CLL, including (1) family history of a first-degree relative with hematologic malignancy including lymphomas, leukemias, and myeloma; (2) a history of working or living on a farm; (3) hairdressers; and (4) a history of hepatitis C infection. Protective factors included a history of allergies, blood transfusions, sun exposure, and smoking.

FAMILIAL CHRONIC LYMPHOCYTIC LEUKEMIA

Up to 10% of CLL patients have a first- or second-degree relative with CLL, making CLL one of the most common types of malignancy with familial predisposition. The higher frequency of monoclonal B-cell lymphocytosis (MBL) reported in these families provides further evidence of inheritance in a subset of patients. However, unlike other types of familial cancers, it is very uncommon for CLL patients to have large pedigrees with many affected distant relatives throughout an extensive family tree. Rather, the more common finding is for most patients to have one or two first- or second-degree relatives with this diagnosis. Large, case-control studies concluded that the risk ratio (RR) for first-degree relatives of CLL probands to also have CLL was higher than that for most other cancers. Although the average RR for all cancers in a U.S. study was approximately 2.1, CLL showed an RR of 5.0, the fourth highest of all cancers. Relatives of patients with CLL also appear to have a higher frequency of other lymphoproliferative disorders and autoimmune diseases. Unlike a variety of other cancers that have known predisposing genes, identification of divergent genes in CLL has been generally unsuccessful. Multiple association studies have identified numerous putative genes, polymorphisms, and genetic factors including death-associated protein kinase (DAPK) and LEU7 (CD57), IRF4, BAK, CD38, CD5, tumor necrosis factor (TNF)-α, and others, but weak evidence for linkage and conclusive studies demonstrating strong mechanistic contribution to pathogenesis are lacking. The role of anticipation in identifying other family members has been reported by several groups; patients with such a family history are generally diagnosed a median of 10 years earlier than other patients. However, other clinical features of CLL at diagnosis do not appear to be different. Thus, patients with familial CLL do not appear to be genetically or clinically different from individuals with sporadic CLL.

PATHOBIOLOGY

The complexity of the biology of CLL has become increasingly apparent, as the knowledge of the basic science of this disease has expanded. Despite these advances, many questions remain unsolved, including (1) the cell of origin from which CLL is derived; (2) the existence of a CLL stem cell as occurs in other leukemias; (3) the biological etiology of the divergent natural histories of immunoglobulin heavy chain variable region (IGHV)-mutated versus unmutated CLL; and (4) the existence and identification of infectious or other naturally occurring

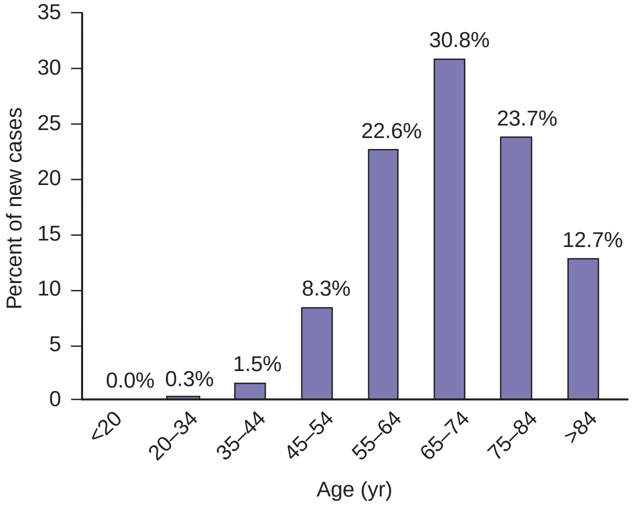

Figure 76.1 Graph demonstrating age distribution of chronic lymphocytic leukemia *(CLL)* as an uncommon diagnosis before the age of 45 years and infrequent (~30% of all patients diagnosed) before the age of 65 years (SEER 21 database, 2014–2018).

antigens that might drive the B-cell clone in this disease. Nonetheless, significant advances in our understanding of the roles of cytogenetics, immunology, and other relevant biological markers in predicting the natural history of disease progression and response to therapy in CLL make an understanding of the basic biology of CLL increasingly relevant and important to clinicians caring for CLL patients.

For many years, CLL was believed to represent a single disease that had a varied natural history. Basic research focused on understanding (1) the normal cell of origin from which CLL is derived; (2) the function of the B-cell receptor (BCR) in CLL; (3) the maturational point in B-cell development at which CLL occurs; (4) the relevance and contribution of a self- or acquired antigen to driving the disease; and (5) the role of the microenvironment in disease development and progression (see Chapter 81). All of these observations are important scientific areas of active, ongoing study, and readers are referred to several recent definitive reviews and Chapter 81 for further information on the basic biology of CLL. The biology and genetics covered within this chapter focus predominately on areas relevant to clinicians who care for patients with CLL.

B-CELL RECEPTOR PATHWAY AND ITS ROLE IN PATHOGENESIS

Modulation of the BCR plays an integral part in the development and maturation of B cells. Its constitutive activation through antigen dependent or independent signaling provides an important survival signal for the propagation of CLL B cells. Signal transduction occurs through a variety of kinases including LYN, PI3K, SYK, and Bruton tyrosine kinase (BTK) with resultant phosphorylation of PLC-γ2 and induction of downstream second messengers that further modulate cell survival regulators. These kinases have been effectively targeted and result in abrogation of the survival signal and B-cell apoptosis. Combinations of these inhibitors with existing and novel therapeutic agents have already changed the natural history of the disease.

X-linked agammaglobulinemia is a disease characterized by a severe immunodeficiency state that results from deficient BTK (see Chapter 52). Characterization of this defect and its resultant impact on causing severe impairment in B-cell development and humoral immunity has been critical to our understanding of CLL disease biology. Activating mutations of BTK have not been identified in CLL or other cancers but CLL B cells tend to have higher levels of BTK that can be induced through the BCR signaling pathway. The enzyme BTK is at an essential node for survival of CLL cells as deletion of this gene prevents development of CLL in mouse models and pharmacologic inhibition results has similar phenotype. Indeed, ibrutinib was the first-in-class irreversible, covalent, BTK inhibitor that efficiently targets BTK resulting in significant abrogation of downstream survival signaling transduced through this pathway and inhibition of cell survival and proliferation. Multiple other BTK inhibitors have also shown similar results. These include both reversible and non-covalent BTK inhibitors. Similarly, both SYK and PI3K can be induced by activation of BCR pathway. The PI3-kinase isoform delta inhibitors, idelalisib and duvelisib, and syk inhibitors have been shown to antagonize these survival signals and result in clinically meaningful disease responses.

IGHV Mutational Status

Two seminal manuscripts in 1999 demonstrated that the IGHV gene had undergone somatic mutation, indicating that CLL arose after this point in B-cell maturation, in 60% of patients at diagnosis. Detailed epigenetic studies examining the methylation changes occurring in normal B cells during development have subsequently suggested that immunoglobulin mutational analysis may indicate simply where in normal B-cell development transformation occurred. In an attempt to identify surrogate genes associated with IGHV-unmutated disease, ZAP-70 overexpression was identified. The majority of IGHV-unmutated CLL cells have ZAP-70 expression and demonstrate evidence of syk activation and other essential BCR downstream activation signals after ligation of surface IgM (sIgM) that is related to overexpression of this protein. In contrast, virtually all IGHV-mutated patients lack significant ZAP-70 expression and do not signal after ligation by sIgM, but can often weakly signal through other alternative BCRs. Thus, although gene expression profiling demonstrates all CLL cells to be most closely related to memory B cells, IGHV-unmutated and -mutated CLL cells differ significantly with respect to their ability to transduce intracellular signals after sIgM ligation. A common repertoire of mutational changes among CLL patients has also been documented that differs significantly from that found in the normal adult B-cell repertoire. These studies have prompted the hypothesis that CLL may represent an antigen-driven disease. IGLV3–21-expressing B cells have recently been described in a subset of patients to acquire a single point mutation (R110) that triggers autonomous BCR signaling and which subsequently identifies a subpopulation of CLL patients with a poor outcome. A multitude of mechanisms of BCR activation are indeed present in CLL. Targeting BCR signaling based on this has already resulted in the development of several therapeutic agents directed against signaling pathways downstream of the BCR.

Defective Apoptosis

Since its initial description and early characterization, CLL has been considered a disease of slow accumulation of tumor cells caused by disrupted or defective apoptosis. Multiple studies have demonstrated that CLL cells overexpress several antiapoptotic proteins, including bcl-2, mcl-1, bak, and X-linked inactivator of apoptosis protein (XIAP), and have diminished expression of compensatory proapoptotic proteins such as bax. Overexpression of bcl-2 and mcl-1 and an increase of the ratio of these proteins to bax have correlated not only with disrupted apoptosis but also shortened OS and poor response to therapy. Studies have demonstrated that CLL cells have constitutive activation of several anti-apoptotic transcription factors, including nuclear factor kappa-B (NFκB), nuclear factor of activated T cells (NFAT), and signal transducer and activator of transcription 3 (STAT3). Each of these transcription factors can influence one or more of the antiapoptotic proteins that promote survival in vivo. The source of activation of these different transcription factors is not completely defined but may be partly attributable to autocrine and paracrine networks involving B-cell activation factor (BAFF), a proliferation inducing ligand (APRIL) vascular endothelial growth factor

(VEGF), interleukin-4 (IL-4), and CD40 among others. CLL cells are also maintained through contact with stromal cells (bone marrow [BM] and dendritic) and nurse like cells through a complex interface of adhesion molecules and stromal survival factors such as stromal cell–derived factor-1 (SDF-1). The importance of the in vivo environment to CLL survival is supported by the increase in apoptosis when CLL cells are cultured in vitro. Moreover, targeting the overexpressed anti-apoptotic protein like bcl-2 with a specific bcl-2 inhibitor venetoclax has already led to excellent clinical efficacy.

Genetic Abnormalities

Detailed study of the genetics of CLL is hindered by the inability to effectively induce proliferation of tumor cells for standard metaphase cytogenetic analysis and the poor response of CLL cells to B-cell mitogens (see Chapter 57). Nonetheless, several cytogenetic studies identified a variety of deletions, including del(11q22.3), del(17p13.1), del(13q14), and del(6q21-q23), as well as trisomy 12, as common abnormalities in CLL. The frequency of these abnormalities has been further refined by using fluorescence in situ hybridization (FISH), which does not require isolation of dividing cells. These studies have demonstrated that del(13q14) is by far the most common cytogenetic abnormality in CLL followed by trisomy 12, del(11q22.3), del(17p13.1), and del(6q22.3). Stimulation studies with CpG oligonucleotides plus IL-4 or CD40 confirmed the prevalence of these abnormalities and identified unbalanced translocations not generally observed with traditional metaphase cytogenetics. The prognostic implications of these unbalanced translocations appear to be significant. Similarly, complexity of karyotype appears to be a driving poor prognostic factor in CLL. Interestingly, balanced translocations, which are more frequently observed in ALL and AML, are generally not observed in CLL.

The presence of recurrent deletions in CLL suggests the possibility of unique tumor suppressor genes in these different regions. This was confirmed by the discovery of miR15 and miR16, two noncoding microRNAs, in the deleted region of 13q14. Noncoding RNAs range in size from 21 to 25 nucleotides and represent a class of gene products whose function is to silence genes through binding to the 3′-untranslated region of specific genes to inhibit translation. It was later shown that miR16 regulates expression of bcl-2, which is overexpressed in CLL and other B-cell lymphoproliferative disorders. Multiple studies have associated specific miR expression with rapid disease progression, fludarabine resistance, poor prognosis, and modulation of BCR pathway and bcl-2 signaling. In addition, miR34a has been directly related to the adverse outcome associated with p53 dysfunction.

Recurring Mutations in Chronic Lymphocytic Leukemia

Until the advent of whole-exon and whole-genomic sequencing, CLL was not typically associated with recurring mutations early in the pathogenesis of the disease. Probably best characterized are p53 mutations, which occur in approximately 10% of patients at diagnosis, often in conjunction with deletion of the alternative allele (at 17p13.1 loci) that is associated with rapid disease progression and poor survival. With treatment and subsequent relapse, the frequency of p53 mutations continues to increase proportionately and is most common in patients with Richter transformation. Thus, p53 mutations are considered by most to be a secondary abnormality in CLL associated with progression. Nonetheless, p53 mutations or deletions have significant impact on consideration of treatment of CLL, and conventional chemoimmunotherapy-based approaches have no role in the treatment of patients with this abnormality. Other recurring mutations in CLL, including SF3B1, NOTCH1, MYD88, XPO1, and ERK1 and more than 100 other mutations have been described with varying physiologic significance. A summary of important genetic abnormalities and their impact is provided in Table 76.1.

TABLE 76.1 Summary of Important Prognostic Markers and Their Role in Disease Biology

Prognostic Markers	Frequency (%)	Putative Role in Disease Biology
Del17p/loss of TP53	~7–10	Loss of p53 protein and decreased levels of miR34a results in cell cycle dysfunction. Predicts for poor response to treatment and worse survival
Del11q	~18–20	Results in ATM gene deletion in the majority of patients and subsequently a lack of repair of double-stranded DNA breaks. Predicts for shorter time to treatment failure and survival. Impact may be overcome with the use of alkylator based chemoimmunotherapy
Trisomy 12	~16–20	Impact may be through a gene dosage effect especially of genes encoding CDK4 and MDM2. Predicts for intermediate risk disease
Del13q	~55–60	Results in the loss of miR-15a and miR16-1 along with DLEU7 that results in loss of tumor suppressor activity. Generally associated with favorable outcomes including response to chemoimmunotherapy and survival
NOTCH1 mutation	~10	Constitutive activation of NOTCH1 results in increased cell survival and resistance to apoptosis and predicts for inferior response to rituximab and shorter treatment-free interval
SF3B1 mutation	~9–18	Mutually exclusive with NOTCH1 mutations. May cause abnormal transcription and splicing events. Associated with rapid disease progression
BIRC3 mutation	~5	Associated with unmutated IGHV, a shorter treatment free interval, and del11q. Mutually exclusive with TP53 mutations
MYD88 mutation	~3–13	Important adapter of the IL-1 and toll-like receptor pathway. Gain-of-function mutations result in increased cytokine production and activation of the NF-κB pathway. Associated with improved survival

Immune and Micro-Environmental Features

The importance of progressive immune suppression with progression of CLL has become appreciated in both human CLL and murine models of this disease. The absolute number of T cells and natural killer (NK) cells in CLL patients at diagnosis has been shown to predict OS. In particular, expansion of suppressive T-regulatory cells has been documented as patients approach the time of requiring therapy. The immunosuppressive effects observed in CLL lie predominately with the CLL clone as demonstrated in human and mouse models of CLL. Similarly, the importance of microenvironmental compartments of CLL such as lymph nodes and BM, where stromal cells provide proliferative signals as well as survival signals to protect from apoptosis, are recognized. Derived from this work are biomarkers of measurable chemokines responsible for T-cell recruitment to the microenvironment. Given the link of these stimuli to BCR signaling, inhibitory molecules directed at kinases involved in this interaction have resulted in significant clinical advances.

CLINICAL MANIFESTATIONS

At diagnosis, CLL most often does not have clinical manifestations associated with the disease. For early-stage CLL patients, the diagnosis is often identified as part of routine blood tests for evaluation of an unrelated problem such as infection, kidney stone, or preoperative assessment in which an elevated leukocyte count is noted with increased numbers of mature lymphocytes observed on the blood smear. For a much smaller subset of patients with CLL, presentation of disease occurs as a consequence of fatigue, weight loss, early satiety (from spleen enlargement), petechiae (from low platelets), or new palpable lymph nodes. Patients with symptomatic CLL at diagnosis represent only 15% of those seen, due to the more indolent nature of this disease at diagnosis. With additional follow-up, the majority of CLL patients will eventually manifest symptoms of the disease that ultimately lead to the need for treatment. The most common symptoms of progression include increasing fatigue (as a consequence of anemia and cytokines from disease), increasing lymph node and spleen size, worsening hematologic parameters (anemia and thrombocytopenia), and rarely infiltration of other organs (kidney, lung, pleural space, skin) that necessitates initiation of treatment to palliate symptoms. Unusual symptoms generally not associated with CLL progression are night sweats, fevers, and weight loss. These are generally suggestive of Richter transformation.

Separate from direct CLL progression, the disease is also immunosuppressive, and with more advanced disease, an increase in infections is generally observed. This represents a major morbidity of CLL and is a leading contribution to mortality associated with this disease. Other manifestations of immune suppression, including higher rate of secondary malignancies and autoimmune complications, are also increased in CLL (see box on Initial Evaluation of Young Patients With Chronic Lymphocytic Leukemia).

DIAGNOSIS AND LABORATORY MANIFESTATIONS

The diagnosis of CLL, as defined by the International Workshop on Chronic Lymphocytic Leukemia (iwCLL) 2018 criteria, requires an absolute malignant B-cell lymphocyte count of greater than 5000/μL that co-express CD5 and CD23 on peripheral blood immunophenotyping. Morphologically, the lymphocytes must appear mature with fewer than 55% prolymphocytes (Fig. 76.2A–E). The BM aspirate smear if done should show greater than 30% of all nucleated cells to be lymphoid, or the BM core biopsy must show lymphoid infiltrates consistent with CLL (see Fig. 76.2F and G). The overall cellularity must be normocellular or hypercellular. Immunophenotyping must reveal a predominant B-cell monoclonal population coexpressing the B-cell markers CD19, CD20, and CD23 and the T-cell antigen CD5 in the absence of other pan-T-cell markers (see later section). In some cases a hypocellular marrow can be present as an artifact of marrow aspiration.

Patients may present with tumor cells immunophenotypically consistent with CLL but have predominately lymph node disease or organomegaly, without a peripheral B-cell lymphocyte count of 5000/μL despite BM involvement. These patients are considered to have small lymphocytic lymphoma (SLL) and both entities share similar immunophenotypic features, genetic findings, natural history, and complications. The clinical management of SLL patients should be similar to CLL with respect to diagnostic testing and treatment.

INITIAL EVALUATION OF YOUNG PATIENTS WITH CHRONIC LYMPHOCYTIC LEUKEMIA

Only 10% of patients diagnosed with CLL are younger than 50 years of age, and these patients often present a diagnostic and therapeutic dilemma to hematologists initially evaluating them. The great majority of patients diagnosed before the age of 50 years will have early-stage CLL with a slightly higher incidence of a prior first-generation relative with this disease. Additionally, these patients are generally of a higher economic status or have chronic fatigue or medical illnesses for which they have been undergoing routine blood testing, leading to diagnosis of CLL. When the diagnosis of CLL is made, these younger patients have a more challenging time understanding how the disease will impact them. For patients with no symptoms referable to CLL, we generally discuss complications of the disease during the first visit and have a detailed discussion regarding assessment of genetic risk factors predisposing to early disease progression, including select interphase chromosomal abnormalities [del(17p13.1) and del(11q22.3)] and IGHV mutational status (unmutated). During this time, it is important to counsel patients that identification of high-risk genomic features can actually increase anxiety because no treatment intervention is indicated in the absence of symptoms, regardless of genomic profile, outside of a clinical trial. In our experience, the great majority of patients desire this testing. We provide considerable discussion about the excellent outcomes with novel agents and the limited role of chemotherapy for the management of this disease. Despite the potential benefit of allogeneic SCT in younger patients with CLL and possibility of a curative option, we generally avoid mention of this option and do not pursue consultation or tissue typing of patients or siblings. More recent advances with chimeric antigen receptor T-cell (CAR-T) therapy are occasionally mentioned. During the second visit 4 to 6 weeks later, we review the results of these prognostic factors and answer additional questions that have arisen, and reiterate the rationale behind active surveillance and the lack of improvement in OS with early intervention. Since “watchful waiting” is a difficult concept to grasp by a patient who has recently been diagnosed with a malignancy, we use “active surveillance” as a preferred term for our management approach. Ultimately, the majority of patients have low-risk disease, and knowing this allows patients to take partial control of their disease and move on with their lives. Serial assessment of the psychological well-being of patients with CLL during this first year is incredibly important. At no place during the evaluation do we refer to CLL as being a good or favorable leukemia. In our experience, the most common reason for dissatisfaction toward the initial hematology evaluation is lack of explanation of the disease process or the minimization of CLL as a “good leukemia to have.”

For young patients presenting with other chronic medical problems who are asymptomatic from their CLL, we follow the approach outlined above. More commonly, these patients have fatigue, mild anemia, or other symptoms that could be referable to the CLL. Additionally, this group is more commonly overweight or obese. In either setting, it is important to first think like an internist and pursue other causes for symptoms potentially referable to CLL. In particular, an effective weight loss and exercise plan often results in improvement in quality of life and reduction in symptoms of fatigue, along with better control of other medical comorbidities. In some cases methylphenidate can be effective for the management of CLL related fatigue. It is very important to note that younger patients with CLL can often go a decade or more without therapy, and early treatment of this patient group in the absence of symptoms still offers no proven long-term advantage. For this reason, we remain very conservative on starting therapy for young patients with CLL unless they have high-risk disease and are treated on a clinical trial. To date, trials with chemotherapy, chemoimmunotherapy, and BTKi have not demonstrated survival differences with early intervention although follow-up with the later therapies is short.

MONOCLONAL B-CELL LYMPHOCYTOSIS

The increase in diagnostic blood testing for other medical conditions and easy availability of immunophenotyping has led to recognition of a precursor condition to CLL called MBL. Patients with MBL have circulating peripheral blood B cells immunophenotypically consistent with CLL but do not have enlarged lymph nodes, a malignant lymphocyte count greater than 5000/μL, cytopenias, organomegaly, extramedullary involvement, or other features of a lymphoproliferative disorder. Immunophenotyping can further classify this entity into three separate categories: (1) CLL-type MBL; (2) Non-CLL type MBL; (3) Atypical CLL-type MBL. Care must be taken to

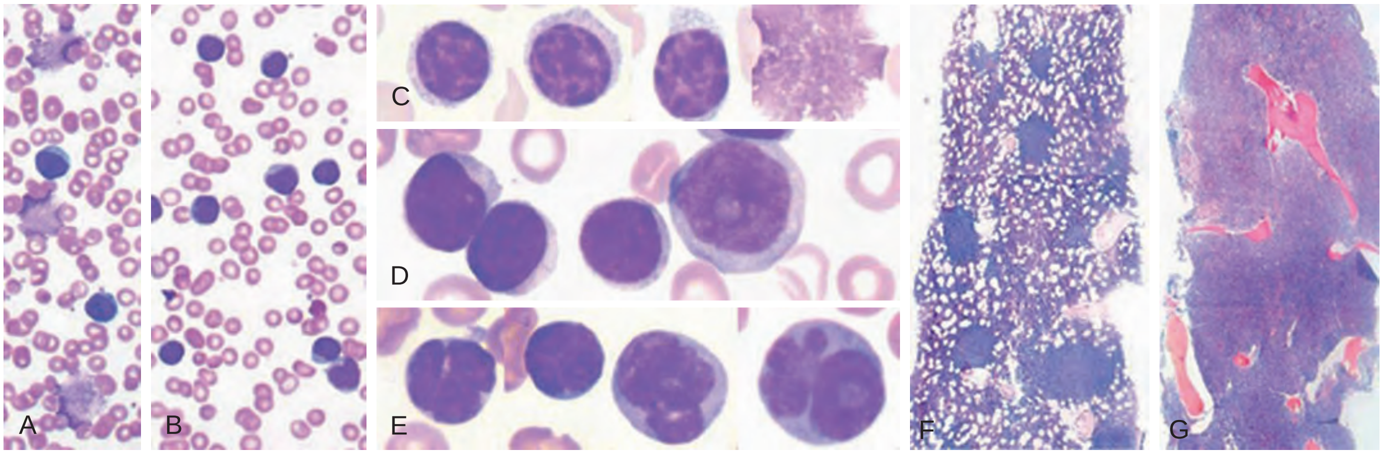

Figure 76.2 CHRONIC LYMPHOCYTIC LEUKEMIA (CLL). The peripheral blood smear (A) typically shows lymphocytosis and increased smudge cells as a result of the fragility of the CLL cells (see also smudge cell in C, *right side*). These can be avoided by making a preparation of blood and bovine serum albumin (22%) at a ratio of 11 drops of blood and 1 drop of albumin before preparing the slide (B). Cytologic features of CLL cells differ. Classic cells have a small nucleus with a "soccer ball" chromatin pattern (C). Some cases have increased large cells, or prolymphocytes, with more open chromatin and prominent "punched-out" nucleoli (D; prolymphocyte, *right side*). Other cases, sometimes referred to as "atypical," have clefted cells and large cells (E). The bone marrow can show nodular infiltrates of CLL cells (F), an interstitial infiltrate, or a diffuse infiltrate (G).

differentiate this entity from circulating disease frequently observed in a variety of non-Hodgkin lymphomas (NHLs).

The frequency of MBL increases with age; 0.3% of patients younger than the age of 40 years have MBL compared with 3.5% to 6.7% of 40- to 60-year-old patients and 5% to 9% of 60- to 90-year-old patients. The frequency of MBL in family members of patients with a first-degree relative with CLL is significantly higher in both young and older patients. Similar to the relationship of monoclonal gammopathy of undetermined significance and multiple myeloma, it appears that only a small proportion of patients with MBL develop overt CLL over time. These are mostly patients with high count MBL, defined as a monoclonal B-cell count of 500 to 5000/μL with a risk of progression to CLL of 1% to 2%/year. However, a similar incidence of 1%/year has also been reported in patients with low count MBL (<500/μL) despite earlier studies suggesting minimal risk of progression. Since the classification of SLL is based on lymphadenopathy evaluated on physical examination, patients with MBL who are found to have lymphadenopathy on CT scans are frequently misclassified as SLL. These patients without palpable lymphadenopathy and only limited adenopathy on imaging have similar risk of progression as patients without lymphadenopathy on imaging with concurrent MBL. We therefore do not recommend the routine use of CT scans in the initial workup or routine follow-up of patients with CLL, SLL, or MBL. Similarly, the degree of BM involvement is not correlated with risk of progression, and while the diagnostic criteria for MBL does not include BM involvement, the presence of BM disease alone does not change the diagnosis from MBL to CLL or SLL.

Patients with MBL are generally evaluated similarly to patients with early-stage CLL with comprehensive prognostic testing and IGHV mutational status and cytogenetic and mutational abnormalities. They also generally have many of the long-term complications of CLL related to immune suppression including a higher frequency of infections and secondary malignancies. We therefore approach the initial counseling of these patients in a similar manner as newly diagnosed CLL patients with respect to interventions (vaccines, dermatologic evaluation, and education) to minimize these complications. We also continue to follow these patients with yearly blood counts and exams.

LABORATORY MANIFESTATIONS

For many years, the diagnosis of CLL was made based on morphologic examination of the peripheral blood smear, which demonstrated mature lymphocytes with an abundance of smudge cells. Despite rigorous morphology, many diseases can mimic CLL in both appearance and clinical presentation, as summarized in Table 76.2, resulting in incorrect diagnoses. With the advent of new, more effective targeted therapies in CLL and other related diseases listed in Table 76.2, determining the correct diagnosis is of great importance. Flow cytometry, or immunophenotyping, is now the standard approach to establish the diagnosis of CLL (Fig. 76.3, for example). The diagnosis of CLL relies on immunophenotypic confirmation, and flow cytometry should therefore be performed on all CLL patients at diagnosis. CLL cells have a relatively consistent immunophenotype, which differentiates CLL from mantle cell lymphoma, hairy cell leukemia, follicular lymphoma, marginal zone lymphoma, and other indolent B-cell malignancies. Specifically, CLL cells express a variety of B-cell markers, including dim sIg, CD19, dim CD20 and CD23, CD200, as well as the pan-T-cell marker CD5. κ or λ restriction is always present, establishing the presence of a clonal B-cell population, although sIg expression may be so dim that light chain restriction may be difficult to determine. In contrast, the presence of CD10, FMC7, or CD79b (all typically absent on CLL cells) or bright expression of CD11c, CD20, or CD25 (all typically dim on CLL cells) suggests an alternative low-grade B-cell lymphoproliferative malignancy. Expression of CD5 without CD23 suggests mantle cell lymphoma (see Chapter 86), and FISH for t(11;14) should be performed to exclude mantle cell lymphoma. Some genetic subsets of CLL are predisposed to variant antigen expression, particularly patients with trisomy 12. Repeating immunophenotyping after the initial diagnosis is not required unless there is a suspicion of transformation to a more aggressive histology or there is a need to assess BM response or antigen expression for an antibody-directed therapeutic agent. Transformation of CLL (Fig. 76.4A–C) to either prolymphocytic leukemia (PLL) or large cell lymphoma (Richter transformation) is often associated with

TABLE 76.2 Diseases That Can Mimic Chronic Lymphocytic Leukemia

- Follicular lymphoma
- Mantle cell lymphoma
- Marginal zone lymphoma
- Hairy cell leukemia
- Acute lymphoblastic leukemia
- T-cell prolymphocytic leukemia
- Large granular natural killer or T-cell leukemia

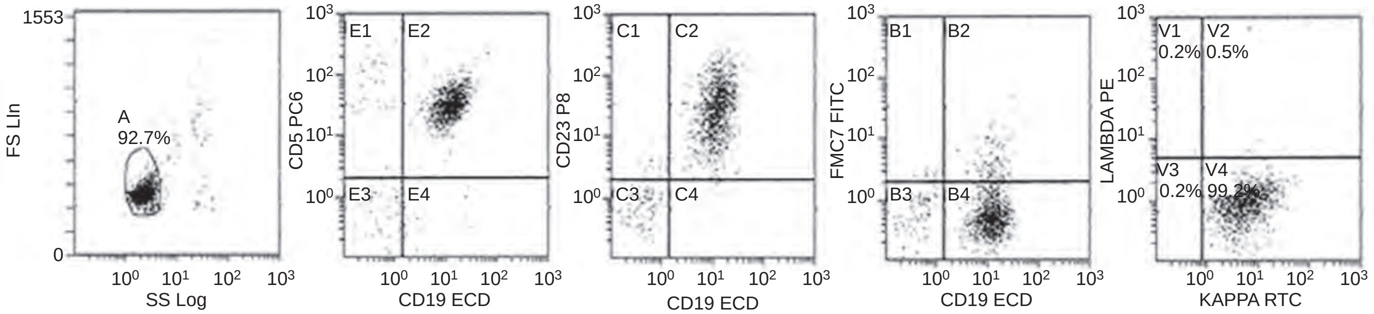

Figure 76.3 FLOW IMMUNOPHENOTYPING IN CHRONIC LYMPHOCYTIC LEUKEMIA (CLL). Flow data in a typical case of CLL. The phenotype is CD19$^+$ clonal B cells with κ light chain restriction (weak to moderately intense), with coexpression of CD5 and CD23, but lack of FMC-7. The cells were CD38-negative.

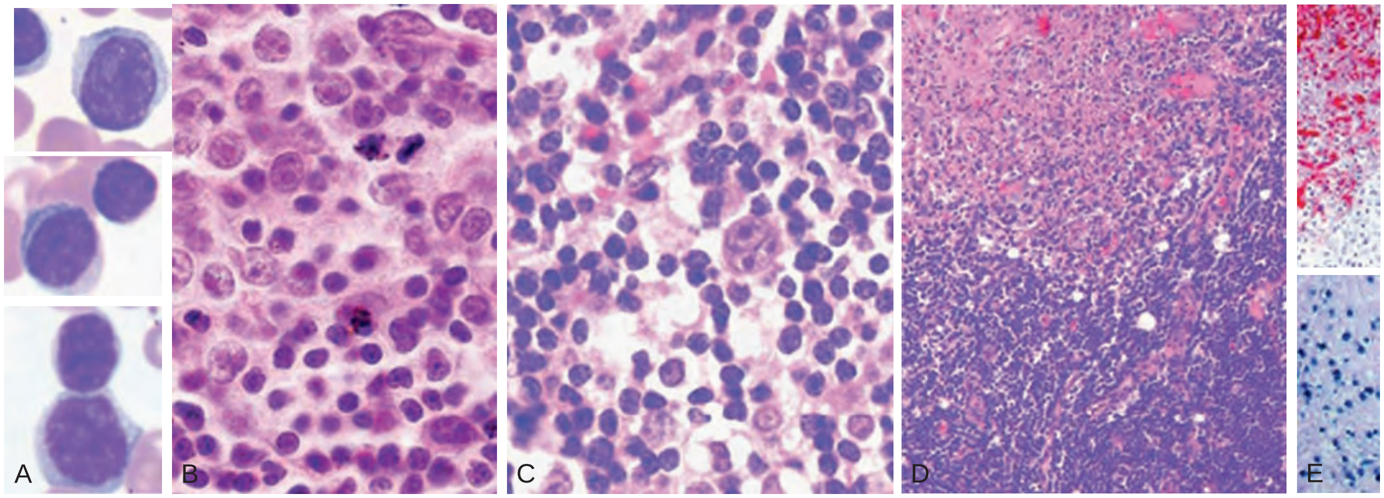

Figure 76.4 TRANSFORMATION IN CHRONIC LYMPHOCYTIC LEUKEMIA (CLL). Some patients of CLL develop increasing numbers of prolymphocytes (A) and a "prolymphocytic transformation." A Richter transformation is to a large-cell lymphoma (B; large cells, *upper left*, residual CLL, *lower right*). Occasionally, cases can transform to Hodgkin lymphoma (i.e., the Hodgkin variant of Richter syndrome) (C). With the use of fludarabine and other immunosuppressants, patient can also develop Epstein-Barr virus–related lymphadenopathies or lymphadenopathies with large areas of necrosis caused by herpes simplex virus (HSV). The case illustrated in (D) and (E) had both (E; *upper panel* shows an immunostain of HSV-1/2, and lower is EBER in situ hybridization).

immunophenotypic drift, where CD5 is lost and FMC7 expression is acquired. Additionally, expression of CD20 and surface immunoglobulin typically becomes brighter in PLL or Richter transformation. Although the morphologic appearance of prolymphocytes or large lymphoid cells in blood, BM, or lymph nodes is typically adequate to make the diagnosis of transformation, immunophenotyping may be useful in cases when morphologic findings are less clear.

Patients with CLL often present with no symptoms, with the diagnosis being made as a consequence of asymptomatic enlarged lymph nodes or splenomegaly detected on physical examination or routine blood work done for another cause. Other patients present with symptoms of BM replacement (fatigue, dyspnea, or petechiae secondary to anemia and thrombocytopenia), symptomatic lymphadenopathy or hepatosplenomegaly, autoimmune complications (hemolytic anemia or idiopathic thrombocytopenic purpura), or B symptoms (fevers, night sweats, and weight loss). A small proportion of CLL patients will have pulmonary infiltrates at diagnosis that are representative of CLL involvement in some cases and active infection in others.

In addition to blood and BM lymphocytosis, a few abnormal laboratory findings are commonly observed in CLL. Neutropenia, anemia, and thrombocytopenia can develop as a consequence of BM infiltration or myelosuppressive therapy administered to eliminate the leukemia. A positive direct antibody, or Coombs, test result is observed in approximately 10% to 25% of CLL patients at some time during the course of the disease. Similarly, autoimmune thrombocytopenia or neutropenia may be present, although other causes such as BM replacement or a chemotherapy effect are much more common and should be excluded. Pure red blood cell (RBC) aplasia can sometimes be observed with isolated anemia and absence of RBC precursor cells (see Chapter 33). Hypogammaglobulinemia is common in CLL and becomes more frequent and marked as the disease progresses. A monoclonal protein, most commonly IgM, can be present in a subset of CLL. By contrast, hypercalcemia and a markedly elevated lactate dehydrogenase (LDH) level are not common in CLL and suggest progression to Richter transformation. Clearly, a wide spectrum of presentations exists for patients with CLL.

PROGNOSIS

Historically, patients with CLL were staged using either the Rai or Binet system. Both of these discriminate CLL by the sites of disease and degree of cytopenias induced by BM replacement by the leukemia cells. Patients can be categorized into three groups on the basis of these features. According to the modified Rai criteria, patients in the low-risk group (stage 0) have lymphocytosis without any other abnormality; patients in the intermediate-risk group (stages I and II) have, in addition to their lymphocytosis, enlarged lymph nodes, spleen, or liver; and patients in the high-risk group (stages III and IV) have anemia (hemoglobin <11.0 g/dL) or thrombocytopenia (platelets <100 × 10^9/L).

TABLE 76.3 Rai Staging System

Rai Stage at Diagnosis	Percent of Patients Never Requiring Chronic Lymphocytic Leukemia Therapy	Expected Survival in Months From Initial Diagnosis
0—Lymphocytosis >5 × 10^9/L only	59	150
1—Lymph node enlargement	21	101
2—Spleen or liver enlargement	23	71
3—Anemia with hemoglobin <11 g/dL	5	19
4—Thrombocytopenia <100 × 10^{12}/L	0	19

Adapted from Rai KR, Sawitsky A, Cronkite EP, Chanana AD, Levy RN, Pasternack BS. Clinical staging of chronic lymphocytic leukemia. *Blood*. 1975;46(2):219–234.

The historical median survival times for the Rai low-, intermediate-, and high-risk groups are similar to those of Binet stages A, B, and C: 12+, 8, and 2 years (Table 76.3). For early-stage patients with CLL (Rai low and intermediate stage and Binet stages A and B), a significant range of time to developing symptoms of CLL exists. The lack of survival advantage with early treatment, the observation that a subset of CLL patients will never require therapy, and the varied natural history of the disease have resulted in the identification of specific biologic or clinical prognostic factors that predict time to progression. Multiple tools have been developed and validated to address this issue, and the CLL-International Prognostic Index (CLL-IPI) score appears to have the most discriminative ability for predicting disease progression and OS in patients with newly diagnosed and previously untreated CLL. This weighted score incorporates five prognostic factors including age, clinical stage, β2-microglobulin, IGHV mutational status, and del17p or TP53 mutation status, with del17p or TP53 mutation status being the most significant variable. This allows separation of patients in low-risk to very high-risk cohorts with respect to survival outcomes, and also provides management suggestions, e.g. active surveillance in patients in the low-risk group. Given the impact of BTKi and other targeted therapies for CLL, the impact of historical staging systems relative to survival for newly diagnosed patients is limited.

Although lymphadenopathy is a common clinical feature of CLL and is incorporated into both major clinical staging systems, computed tomography (CT) scans are not commonly used to determine staging or to evaluate response to therapy outside of clinical trials. However, several studies have examined whether the incorporation of CT scans in initial staging or response evaluation may affect the ability to predict disease progression at diagnosis and assessment of clinical response to therapy. Although a few studies have suggested that these may help predict disease progression at diagnosis, studies done serially at the time of treatment and for response show that CT scans generally do not impact assessment of response, progression-free survival (PFS), or OS. Additionally, CT scan identification of new nodal areas did not impact decisions for retreatment. Thus, routine CT scans should not be performed for staging and response evaluation in CLL. Similarly, PET scans appear to be sensitive for Richter transformation, with a high negative predictive value, but specificity is poor. We generally use these studies to identify patients who warrant biopsy for suspected Richter transformation and to localize where to biopsy.

With recent advances in the molecular biology of CLL, some prognostic factors such as BM infiltration pattern, which requires an invasive procedure at diagnosis, have not maintained their usefulness in predicting disease progression. Prognostic features outside of the traditional staging systems outlined above relative to daily practice are summarized in Table 76.4.

TABLE 76.4 Evaluation of Chronic Lymphocytic Leukemia Patients at Diagnosis

History

- B-symptom and fatigue assessment
- Infectious history assessment
- Occupational assessment for chemical exposure
- Familial history of CLL and lymphoproliferative disorders
- Preventive interventions for infections and secondary cancers

Physical Examination

Laboratory Assessment

- CBC with differential
- Morphology assessment of lymphocytes
- Chemistry, LFT enzymes, LDH
- Flow cytometry assessment to confirm immunophenotype of CLL
- Serum immunoglobulins
- Serum β_2M levels
- Interphase cytogenetics for del(17p13.1), del(11q22.3), del(13q14), del(6q21), and trisomy 12
- IGHV mutational analysis
- Stimulated metaphase karyotype (if available)

Selected Tests Under Certain Circumstances

- DAT, haptoglobin, reticulocyte count if anemia present
- CT scan if unexplained abdominal pain or enlargement present
- PET scan or biopsy (or both) if large nodal mass present
- BM aspirate and biopsy if cytopenias present
- Familial counseling if first-degree relative with CLL

Teaching

- Varicella zoster identification instruction
- Skin cancer identification
- Disease education (Leukemia and Lymphoma Society)

BM, Bone marrow; *CBC*, complete blood count; *CLL*, chronic lymphocytic leukemia; *CT*, computed tomography; *DAT*, direct antiglobulin test; *LDH*, lactate dehydrogenase; *LFT*, liver function test; *PET*, positron emission tomography.

Thymidine Kinase Activity and β_2-Microglobulin

Thymidine kinase is an enzyme involved in the salvage pathway of DNA synthesis and correlates with proliferative activity. Elevated thymidine kinase activity (TKA) has been observed to be predictive of early progression in a subgroup of untreated patients with early-stage CLL. β_2-Microglobulin (β_2M) is an extracellular protein component of the human leukocyte antigen (HLA) class I complex. β_2M has been shown to have significant prognostic relevance in lymphoma and multiple myeloma and correlates with disease burden in CLL. Both these variables have been validated as independent predictors of shortened PFS, and shorter survival time for both untreated and previously treated patients. Elevated β_2M was also observed in patients with high tumor burden and extensive BM infiltration. In addition to disease progression, both β_2M and TKA have been associated with short duration of remission and inferior survival after treatment with chemoimmunotherapy. In some studies, β_2M also predicts for shorter remission after targeted therapies as well.

IGHV Mutational Status and Surrogates

Although the malignant cell of CLL morphologically resembles a mature lymphocyte, genetic, immunologic, and phenotypic studies suggest that this cell is better designated as either a pregerminal or postgerminal B cell. Somatic mutations in the first and second complementarity-determining regions (CDR1 and CDR2) of the IGHV genes are thought to occur in the germinal centers. Examination of IGHV genes in patient cells suggests that there are two subsets of CLL: leukemias whose cell of origin has successfully traversed the germinal center, resulting in the mutated IGHV phenotype, and leukemias that are derived from naive B cells with the unmutated (germline) IGHV sequence. Whereas approximately 60% of CLL patients have cells with mutated IGHV genes (<98% sequence homology to germline), the remaining patients have cells exhibiting unmutated IGHV (≥98% sequence homology with germline), typical of pregerminal B cells. The prognostic significance of the absence of IGHV gene mutations is substantial, with studies uniformly noting an inferior survival and high predisposition to requiring early treatment in this patient subset. A CLL Research Consortium study examined the impact of IGHV mutation in 307 untreated CLL patients enrolled in a prospective tissue collection study. A total of 53% of these patients exhibited unmutated IGHV genes, and this population had a significantly shorter median time to initial therapy (3.5 years) than those with mutated IGHV (9.2 years; $P < .001$). IGHV 3–21 rearrangements irrespective of low or high concordance with germ line sequence have poor outcome. This can be further refined by the presence or absence of the single point mutation (R110) that triggers autonomous BCR signaling with shorter time to treatment and inferior outcome with chemoimmunotherapy. The impact of this abnormality on targeted therapeutics for CLL is uncertain at this time.

While IGHV testing is widely available, its utilization in routine clinical practice has historically been dismal, with less than 20% of patients being tested for this mutation. Alternative markers that correlate with IGHV mutation status are also frequently utilized and include expression of the cell surface molecule CD38 on CLL cells and ZAP-70 intracellularly, among others.

High CD38 (>30%) expression is associated with both a shorter time from diagnosis to treatment and inferior survival. CD38 interaction with its ligand, CD31, in the presence of IL-2 results in upregulation of the survival receptor CD100 exclusively on proliferating CLL cells. This occurs with concomitant down-modulation of CD72, a negative regulator of immune response. The interaction between CD38 and CD100 on CLL cells and CD31 and plexin B1, respectively, on transfected fibroblasts results in enhanced survival and growth of CLL cells. Furthermore, the presence of nurse-like cells in CLL patients expressing high levels of CD31 and plexin B1 corroborates the interplay of CD38 and CD31 and provides further evidence of activation of circulating CD38-positive CLL cells by the microenvironment. This finding also may explain the aggressive nature of these CLL clones.

ZAP-70 is a T-cell receptor–associated tyrosine kinase that is aberrantly expressed in CLL cells, and ZAP-70 expression is generally found in patients with unmutated IGHV but not in patients with mutated IGHV. Functional studies in ZAP-70 positive cases (>20%) have shown that BCR ligation leads to increased phosphorylation of cytosolic proteins (Syk, BLNK, PLCγ), calcium mobilization, degradation of IκB, and ultimately NFκB target gene activation. Despite clear data showing that ZAP-70 is a prognostic factor, the reproducibility of this assay across laboratories has been problematic. Methylation of select regions in the proximal 5′ region of the ZAP-70 gene has been shown to correlate closely with expression of ZAP-70 and influence treatment outcome and has been utilized as an alternative to ZAP-70 testing. Overall, despite the apparent usefulness of ZAP-70 in research laboratories for discriminating CLL patients at high risk for progression, this test is of limited utility for routine clinical practice.

Other Prognostic Markers

Various other markers are utilized for predicting disease course of CLL. Serum LDH levels are associated with aggressive disease and with Richter syndrome and prolymphocytic lymphoma. Similarly, patients with a lymphocyte doubling time (LDT) of 12 months or less have been shown to have worse overall and treatment free survival. Other markers include soluble factors like CD23, CD44, VCAM-1, CD27 and MMP-9, IL-6, IL-8, miR-15a and miR-16-1, etc. However, none of these are routinely utilized in clinical practice.

Chromosomal Aberrations

Conventional metaphase cytogenetics can identify chromosomal aberrations in only 20% to 50% of CLL cases because of the low in vitro mitotic activity of CLL cells (see Chapter 57). Abnormalities noted in descending frequency of occurrence include trisomy 12; deletions at 13q14; structural aberrations of 14q32; and deletions of 11q, 17p, and 6q. In addition, a complex karyotype (three or more abnormalities) occurs in approximately 15% of patients and predicts for rapid disease progression, Richter transformation, and inferior survival. The use of CD40L or the combination of IL-2 and CpG stimulation revealed translocations in 33 of 96 patients (34%). These translocations were both balanced and unbalanced, occurring in 13q14, 11(q21q25), 14q32, or regions also seen in lymphomas such as 1(p32p36), 1(q21q25), 2(p11p13), 6(p11p12), 6(p21p25), and 18q21. These data define a prognostic subgroup of patients with significantly shorter median time from diagnosis to requiring therapy (24 vs. 106 months) and OS (94 vs. 346 months) compared with those without translocations. The frequency of these translocations in untreated patients is less common, suggesting that these accumulate with disease progression.

Given the limitations of standard or stimulated karyotype analysis, interphase FISH has become the state-of-the-art technique for accurately distinguishing genetic subtypes of CLL. The largest study of interphase FISH resulted in improved sensitivity to detect partial trisomies (12q12, 3q27, 8q24), deletions (13q14, 11q22–23, 6q21, 6q27, 17p13), and translocations (band 14q32) in more than 80% of all cases. In a large study of 325 patients by Dohner and colleagues, a hierarchical model consisting of five genetic subgroups was constructed on the basis of regression analysis of CLL patients with chromosomal aberrations. Patients with a 17p deletion had the shortest median survival time (32 months) and the shortest treatment-free interval (TFI, months); patients with an 11q deletion followed closely with 79 months and 13 months, respectively. Whereas the favorable 13q14 deletion group had a long TFI of 92 months and a median survival of 133 months, the group without detectable chromosomal anomalies and those with trisomy 12 fell into the intermediate group with median survival of 111 and 114 months, respectively, and TFI of 33 and 49 months, respectively. According to this pivotal study, CLL patients are prioritized in a hierarchical order (deletion 17p13 > deletion 11q22-q23 > trisomy 12 > no aberration > deletion 13q14). The hierarchical model of cytogenetic abnormalities in predicting disease progression by FISH has been further confirmed by other studies. Of interest, patients with high-risk interphase cytogenetic abnormalities or other complex abnormalities are almost always found to have IGHV-unmutated CLL. The impact of high-risk interphase cytogenetics relative to disease progression, outside of its association with IGHV-unmutated CLL, in at least one study had less impact on outcome.

Mutational Analysis

Numerous recurrent mutations and or deletions have been described in CLL that are often associated with IGHV mutational status. While the majority of these abnormalities do not impact clinical outcome of CLL, several including p53, ATM, NOTCH1, SF3B1, XPO1, and BIRC3 have been shown to impact time to initiation of treatment and also OS. Outside of p53 mutations, the frequency of these are often low and therefore prevent definitive independent determination of impact on outcome with respect to other features. Several other mutations including ERK1, BRAF, and MYD88 may afford themselves to therapeutic targeting with novel agents that are FDA approved or in clinical trials. Despite routine mutational tests being available, it is not our practice to examine these broadly at diagnosis or at time of treatment. The exception to this is p53 mutations since the presence of both del(17) and p53 mutation predict for a worse clinical outcome as compared to either of these abnormalities alone. We therefore recommend IGHV and p53 mutational testing, along with conventional karyotyping and interphase FISH testing

HOW SHOULD STAGING AND BIOMARKERS BE USED FOR TREATMENT DECISIONS IN CHRONIC LYMPHOCYTIC LEUKEMIA PATIENTS?

Our understanding of the biology of CLL has improved dramatically, and many relevant biomarkers are now available for predicting when CLL will clinically progress. However, no study to date has demonstrated that earlier treatment will alter the natural history of the patient in even the higher-risk groups with high progression rates. Therefore, at the present time, the use of staging and predictive biomarkers should be used only to provide patients with information relative to the expected course of their disease. Outside of a clinical trial, these results should never be used to initiate therapy in patients with asymptomatic disease and are not an indication for treatment. Before performing predictive tests, a detailed discussion of how these tests will be used with the patient should occur and the option of not performing them should be provided. In a subset of patients, significant anxiety can be produced by identifying high-risk features for which observation, without therapeutic intervention, remains the standard of care. Table 76.4 provides an example of the initial evaluation provided by us when seeing a newly diagnosed patient. Because lymphocyte-doubling time is a prognostic feature in the progression of CLL, our approach is to follow patients every 3 months during the first year; if little change in clinical or laboratory parameters occurs at this point, we extend this time period to every 6 months in the absence of new complaints.

for all patients as part of their initial genetic workup for CLL (see box on How Should Staging and Biomarkers Be Used for Treatment Decisions in Chronic Lymphocytic Leukemia Patients?).

TREATMENT

Initiation of Treatment of Newly Diagnosed or Previously Untreated Patients

Many patients are incidentally diagnosed with CLL on routine complete blood count examination and are asymptomatic with a normal hemoglobin and platelet count at time of initial diagnosis. Expectant observation without therapy is the standard practice for such asymptomatic patients, and patients receive treatment only when their disease progresses. This practice is based on several studies that failed to show an improvement in OS when early therapeutic intervention with chlorambucil therapy was administered to asymptomatic patients. A meta-analysis of 2048 patients in six trials demonstrated no difference in death rate between patients who were randomized to early therapy (42.6%) and those with treatment deferred (41.6%). Thus, patients with asymptomatic or early-stage disease derive no therapeutic benefit from early alkylating agent therapy. However, in these studies, chlorambucil was administered as initial therapy, and chlorambucil achieves complete response (CR) in few patients. Similarly, fludarabine when employed early for patients who do not meet the conventional criteria for treatment resulted in higher response rate but failed to demonstrate a survival advantage. A subsequent CLL7 trial of the German CLL study group of high-risk CLL patients did not demonstrate advantage of even more aggressive chemoimmunotherapy with fludarabine, cyclophosphamide, and rituximab (FCR) in improving OS in this group as compared to observation alone. More recently, early results from the German CLL study group CLL12 trial of early intervention with ibrutinib as compared to placebo in patients with intermediate, high, or very high risk of disease progression, demonstrated longer time to next treatment, event free survival, and progression free survival in patients treated with ibrutinib. However, the incidence of adverse events (AEs) was higher in the ibrutinib arm and no difference in OS was observed after limited follow up. While these are promising early results the long-term outcomes of these patients and clonal evolution of the disease with regard to resistance development to BTK inhibitors remain unanswered questions. We therefore recommend ongoing active surveillance of patients with previously untreated CLL including patients with high- and very high-risk CLL-IPI scores until they meet the iwCLL 2018 criteria for treatment. Early intervention strategies should only be considered on a clinical trial at this time.

TABLE 76.5 Modified Indications for Treatment of Chronic Lymphocytic Leukemia

- Grade 2 or greater fatigue limiting life activities
- B symptoms persisting for ≥2 weeks
- Lymph nodes >10 cm or progressively enlarging lymph nodes causing symptoms
- Spleen or liver with progressive enlargement or causing symptoms
- Anemia (hemoglobin <11 g/dL) referable to CLL
- Thrombocytopenia (platelets $<100 \times 10^{12}$/L) referable to CLL or ITP poorly responsive to traditional therapy
- Severe paraneoplastic (e.g., insect hypersensitivity, vasculitis, myositis) process related to CLL not responsive to traditional therapies

AIHA, Autoimmune hemolytic anemia; *CLL*, chronic lymphocytic leukemia; *ITP*, idiopathic thrombocytopenic purpura; *WBC*, white blood cell.

To establish uniform clinical practice standards and ensure reproducible eligibility criteria for entrance into clinical studies, the iwCLL established guidelines for initiation of treatment. Indications to begin therapy include non-autoimmune cytopenias (hemoglobin <10 g/dL, platelets <100,000/μL); bulky (≥10 cm in longest diameter) or symptomatic lymphadenopathy or splenomegaly (≥6 cm below the left costal margin); disease-related B symptoms (unintentional weight loss ≥10% within the previous 6 months, fevers ≥100.5°F or 38°C for 2 or more weeks without evidence of infection, night sweats for ≥1 month without evidence of infection) or fatigue (ECOG PS 2 or worse; cannot work or unable to perform usual activities); rapid lymphocyte-doubling time (<6 months or ≥50% increase over a 2-month period for an initial absolute lymphocyte count >30,000/μL); or LDT of less than 6 months; and autoimmune hemolytic anemia (AIHA) or thrombocytopenia not controlled with steroids. It is imperative to determine if a patient's symptoms are attributable to CLL or a comorbid medical condition because constitutional symptoms such as fatigue are nonspecific and can be caused by many etiologies in elderly patients with comorbid illnesses. In addition to the official iwCLL 2018 criteria for therapy, an increasing frequency of infections and slowly progressive anemia are other indications that can aid the practicing physician in deciding when to initiate therapy in patients with CLL. A summary of the iwCLL 2018 guidelines for treatment is provided in Table 76.5 with some minimal modifications used by us in our practice.

A useful paradigm for clinical practice is to institute treatment in CLL only for cytopenias or directly referable symptoms. When treatment is necessary, a variety of agents have been examined in clinical trials and are currently approved. Previously detailed biomarkers are used in selecting the initial treatment for CLL. Below, we summarize the findings of clinical studies of different treatments for CLL; where such data exist, we integrate genomic biomarkers as well as clinical features, including age and comorbid illnesses. Different therapies are outlined below with attention to details related to their initial use in previously untreated CLL. Because many of these regimens were also developed in relapsed CLL, these data are also reviewed and later referred to in the section Treatment of Patients With Relapsed Chronic Lymphocytic Leukemia.

TARGETED THERAPY

Treatment of CLL has undergone dramatic changes in the last 5 years and chemotherapy with or without the use of CD20 targeting antibodies now has a very limited role in the management of patients with this disease. For historical perspective and for practitioners in resource-limited areas, readers are advised to refer to previous editions of this textbook for detailed discussions on chemoimmunotherapeutic use. The subsequent therapy discussion will be focused on the role of targeted therapies for the management of patients with CLL. Chemoimmunotherapy-related data will be detailed in reference to the comparison to targeted therapies. These authors rarely rely on chemotherapy or chemoimmunotherapy for CLL outside of the rare individual with young IGHV mutated disease where FCR-based therapy may produce cure, albeit with a 3% to 10% risk of treatment-related myeloid malignancy and extended immune suppression that may be associated with development of other secondary malignancies.

BCR signaling and microenvironmental signals are now known to be important in both proliferation and protection of CLL cells in BM and nodal sites. These findings prompted the introduction of several novel, orally available kinase inhibitors. In particular, agents targeting the δ isoform of PI3-kinase and BTK have established clinical activity and, more importantly, durability of remission over time in refractory CLL patients. Early results from these trials led to the approval of ibrutinib, acalabrutinib, and idelalisib for the treatment of patients with relapsed CLL. The results of these studies are summarized below.

BRUTON TYROSINE KINASE INHIBITORS

BTK inhibitors have been a significant advancement for patients with CLL. They have radically transformed the treatment of CLL in the last few years. Ibrutinib was the first-in-class irreversible, covalent BTK inhibitor of BTK that was approved for all indications in patients with CLL. While the initial approval was for patients with high risk and relapsed disease, this was quickly followed by approvals across all disease states including patients with previously untreated disease. The second-in-class BTK inhibitor acalabrutinib was also approved both for patients with untreated and relapsed disease based on similar exciting data. Both agents are potent, irreversible, covalent inhibitors of BTK. BTK is a tyrosine kinase in the Tec family of tyrosine kinases and is an essential element of the BCR signaling pathway. Genetic knock-out or inactivation of BTK in mice produces predominantly a B-cell defect with absent B1 lymphocytes, diminished B cells, and disrupted BCR signaling. Mutations in BTK in humans result in a more profound humoral immune defect with absent B cells, immunoglobulins, and infections. Preclinical work with these inhibitors demonstrated disruption of BCR signaling and in vivo activity in non-human lymphoma mouse models with documented targeted inhibition of BTK. Preclinical studies also established their role in promoting apoptosis of CLL cells, inhibiting activation of PI3-kinase, ERK1, and NFκB by external microenvironment signals, and also prevention of CLL proliferation. While these agents have differing specificities with regard to kinase targeting, their clinical efficacy and utility are now well established.

Ibrutinib in Untreated Chronic Lymphocytic Leukemia

In the pivotal RESONATE-2, phase III, randomized control trial ibrutinib was compared to chlorambucil in 269 patients over 65 years of age or older with previously untreated CLL. Ibrutinib use resulted in significant improvement in progression free and OS at 5 years (PFS estimates at 5 years: 70% vs. 12%; HR [95% CI]: 0.146 [0.098 to 0.218]; OS estimates at 5 years: 83% vs. 68%; HR [95% CI]: 0.450 [0.266 to 0.761). Overall response rate (ORR) was 92% with ibrutinib with 30% complete remissions. Depth of response also improved with prolonged use of ibrutinib. Most frequent AEs observed with ibrutinib were diarrhea, cough, and fatigue and most of these events improved with ongoing use of ibrutinib. With regard to AEs of special interest, ibrutinib increased the severity of hypertension in 26% of patients. Atrial fibrillation was observed in 5% of patients and major bleeding was observed in 6% of patients. Median PFS was 56 months in patients who discontinued ibrutinib in CR or CRi for toxicity-related or other reasons. Importantly, patients who discontinued ibrutinib because of progressive disease had a median OS of 20 months. Early results from this trial resulted in the approval of ibrutinib for patients with previously untreated disease but more importantly, it also demonstrated that in the event that patients have to discontinue ibrutinib for reasons related to toxicity and if they are in a good disease control state, they can maintain disease control for an extended period of time.

Given the exciting results observed with ibrutinib monotherapy, multiple trials were conducted of ibrutinib in various combinations in comparison to existing treatment options. In the ALLIANCE A041202 phase III study of ibrutinib alone or in combination with rituximab, versus bendamustine and rituximab, 447 patients older than 65 years of age were randomly assigned to either ibrutinib, ibrutinib with rituximab, or bendamustine and rituximab arms. PFS at 2 years was 87% with ibrutinib alone, 88% with ibrutinib and rituximab, and 75% with bendamustine and rituximab. While there was no difference between the ibrutinib-containing arms both these arms were significantly better than the bendamustine and rituximab-containing arm. In addition, serious AEs were much higher for bendamustine and rituximab as compared to ibrutinib-containing arms.

Similarly, the combination of ibrutinib and rituximab was also compared to FCR chemotherapy in the Eastern Cooperative Oncology Group (ECOG) E1912 randomized phase III study of patients with previously untreated CLL over 70 years of age or younger. A series of 354 patients were randomized in a 2:1 manner to ibrutinib and rituximab (IR) versus FCR. At a median follow-up of 3 years, the combination of ibrutinib and rituximab significantly improved PFS and more importantly OS as compared to FCR (PFS estimate 89.4% vs. 72.9% at 3 years; HR, 0.35; $P < .001$; OS estimate 98.8% vs. 91.5% at 3 years; HR, 0.17; $P < .001$). While the incidence of serious AEs was similar in both groups, grade ≥3 treatment-related AEs were experienced by 70% of IR-treated and 80% of FCR-treated patients (odds ratio, 0.56; $P = .013$). A total of 23 deaths were reported (IR cohort, 11; FCR cohort, 11) and the use of FCR resulted in a higher incidence of infectious complications. In addition, similar to results seen with RESONATE-2 trial, the median time to progression or death after discontinuing ibrutinib was 23 months.

Subgroup analysis of the ECOG E1912 study by IGHV mutation status demonstrated that IR was superior to FCR for IGHV-unmutated patients (HR, 0.28; 95% CI, 0.17 to 0.48; $P < .0001$), but not for IGHV-mutated patients (HR, 0.42; 95% CI, 0.16 to 1.16; $P = .086$) with current follow-up. These results clearly demonstrate the superiority of ibrutinib as compared to chemoimmunotherapy-based regimens. The benefit of CD20 antibodies for CLL with ibrutinib is of less value, particularly in the elderly population and not yet tested in trials for younger patients.

FCR and BR chemoimmunotherapy have been the most utilized regimens for the treatment of patients with CLL. One of the arguments that is utilized for the use of FCR in the current era is the long-term follow-up that resulted in a plateau in progression free survival curves over the long term in a select subset (~50%) of patients who have mutated IGHV, and achieve minimal residual disease-negative state after FCR treatment. Patients in this select group had a progression free survival of 79.8% at 12.8 years of follow-up as compared to only 8.7% in patients who had unmutated IGHV. These plateaus in progression free survival have not been seen in patients on BR-based regimens. The prolonged and sustained remissions seen in a small subset of patients treated with FCR definitely raises the issue of a potentially curative option for a group of patients with good risk features. While ibrutinib has not demonstrated improvement in outcomes in this particular subgroup, it appears to be equally effective and with prolonged follow-up it might even establish its superiority in this cohort of patients too. Nevertheless, for young, fit patients with mutated IGHV and requiring treatment, and who might be considered candidates for chemoimmunotherapy, we generally discuss this issue in detail and inform them about the increased risk of secondary malignancies and treatment-related myeloid neoplasms associated with the use of FCR chemotherapy. We generally do not recommend the use of chemoimmunotherapy-based regimens in the current era.

Acalabrutinib in Untreated Chronic Lymphocytic Leukemia

Initial results from a phase IB/II clinical trial of acalabrutinib demonstrated promising efficacy and tolerability and resulted in the approval of acalabrutinib for patients with relapsed and refractory disease. In the subsequent ELEVATE TN multicenter, open label, phase III, randomized clinical trial, 675 patients were randomized in a 1:1:1 manner to acalabrutinib, acalabrutinib plus obinutuzumab (a humanized anti-CD20 monoclonal antibody), or obinutuzumab plus chlorambucil. The trial was designed for patients who would not be ordinarily considered candidates for conventional chemotherapy because of an age of 65 years or older, or younger patients with compromised kidney function or a high comorbidity burden. With a median reported follow-up of 28.3 months, PFS was significantly prolonged in the acalabrutinib-containing arms as compared to obinutuzumab plus chlorambucil (estimated 24-month PFS 93% with acalabrutinib-obinutuzumab (95% CI 87% to 96%), 87% with acalabrutinib monotherapy (95% CI 81% to 92%), and 47% with obinutuzumab-chlorambucil (95% CI 39% to 55%)). While there was improved PFS with acalabrutinib in combination with obinutuzumab, the study was not designed to evaluate this comparison. Future studies examining this question are warranted. Treatments were generally well-tolerated with the most common AE being neutropenia and infectious complications in 30% and 21% of patients in the acalabrutinib plus obinutuzumab arm, 9% and 14% in the acalabrutinib alone arm, and 41% and 8% in the obinutuzumab plus chlorambucil arm respectively. With regard to AEs of clinical interest, atrial fibrillation was observed in 3% versus 4% versus 1%; grade 3 hypertension in 3% versus 2% versus 3%; bleeding events of any grade in 43% versus 39% versus 12% in the acalabrutinib versus acalabrutinib plus obinutuzumab versus acalabrutinib plus chlorambucil arms respectively . Based on these results acalabrutinib was approved for treatment of patients with previously untreated CLL either as a single agent or in combination with obinutuzumab. At time of completion of this chapter, the Elevate R/R trial has been completed, comparing the efficacy of ibrutinib versus acalabrutinib in relapsed, del(11q) and del(17p) CLL patients with a non-inferiority design. This trial demonstrated similar progression free survival with use of acalabrutinib but diminished adverse cardiovascular (atrial fibrillation and hypertension), treatment cessation, and many other AEs when compared to ibrutinib. While this study was performed in high-risk, relapsed CLL, it represents the first to provide support for broad use of acalabrutinib in CLL as the preferred BTKi based upon the favorable side effect profile observed in this trial. A third BTKi zanubrutinib has also been shown to have similar efficacy and improved safety over ibrutinib, but has not been formally approved for the treatment of CLL. We typically use zanubrutinib when patients are intolerant to acalabrutinib or when patients require proton pump inhibitor therapy.

Venetoclax in Untreated Chronic Lymphocytic Leukemia

The bcl-2 antiapoptotic protein is overexpressed in CLL and has been shown to disrupt apoptosis in this disease. Although the bcl-2 antisense molecule Genasense did not meet the bar for regulatory approval in CLL, attempts to target bcl-2 with small molecule inhibitors continued. Another potent inhibitor of bcl-2, navitoclax (formerly ABT263), demonstrated single agent activity in relapsed CLL with a target specific (BCL-XL) dose-limiting toxicity of profound thrombocytopenia. A second-generation oral bcl-2 inhibitor venetoclax (ABT-199) that lacked off-target effect on BCL-xL was subsequently developed. The initial clinical development of venetoclax was complicated by fulminant tumor lysis syndrome especially in patients with high burden of disease, and mitigation strategies were subsequently developed to improve its safety and reduce the incidence of hyperacute tumor lysis. It subsequently demonstrated impressive activity with deep remissions in patients with relapsed and refractory CLL including those with del17p resulting in its initial approval in that patient subgroup.

Given the impressive results seen in patients with relapsed CLL, venetoclax was combined with obinutuzumab and compared to chlorambucil and obinutuzumab in the CLL14 randomized clinical trial of 432 patients. Patients included in this trial would not be ordinarily considered for treatment with chemoimmunotherapy-based regimens and were treated with 12 months of treatment with venetoclax and chlorambucil while obinutuzumab was used at standard dose and schedule. This time-limited combination of venetoclax plus obinutuzumab (12 months) demonstrated a significantly higher PFS at 24 months of 88.2% (95% CI, 83.7 to 92.6) as compared with 64.1% (95% CI, 57.4 to 70.8) with chlorambucil and obinutuzumab. Most common AEs included neutropenia and infectious complications in both arms. There were no episodes of clinical tumor lysis syndrome in patients treated with venetoclax and only 3 patients had laboratory evidence of tumor lysis syndrome. AEs led to discontinuation of treatment in 16% of patients in the venetoclax and obinutuzumab arm and 15.4% of patients in the chlorambucil plus obinutuzumab arm. Treatment with venetoclax was also successful in achieving undetectable measurable residual disease (u-MRD) in 75% of patients in the peripheral blood and 56% of patients in the BM. With longer follow-up, patients treated with venetoclax-based treatment continued to demonstrate improved outcomes in all groups of patients after discontinuation of therapy. However, patients with del17p demonstrated much shorter PFS interval as compared to patients without del17p after discontinuation of venetoclax. Interestingly, patients treated on the venetoclax and obinutuzumab arm had a higher rate of second primary malignancy (17%) as compared to 10.3% in the chlorambucil plus obinutuzumab arm necessitating the need for ongoing routine health maintenance evaluations despite discontinuation of therapy. The resulting approval of venetoclax in combination with obinutuzumab as first-line treatment for patients with CLL therefore provides an effective, time-limited, and generally well-tolerated treatment, which results in sustained remissions despite drug discontinuation.

The choice of a specific novel therapeutic agent as first-line treatment is definitely a difficult decision in the current era and needs to be based on patient preferences, clinical scenarios, comorbid conditions, and cost and insurance issues. The completion of the Elevate R/R trial provides support for acalabrutinib if a BTK is used. While some view venetoclax-based options as attractive based upon providing an option to discontinue treatment after a defined time period, patients will definitely require repeat treatment and long-term disease-free or OS outcomes might be similar in patients with interrupted as compared to continuous treatment strategies. Our general approach is to start treatment with BTK inhibitors unless there is a clear contraindication to their use. We also prefer to utilize acalabrutinib and exclusively use it in older patients (>70 years of age) with documented cardiac comorbid conditions. The benefit of obinutuzumab addition to acalabrutinib represents a question to the field at this time although its use does deepen remission and offers the potential opportunity to discontinue therapy if CR is obtained. We strongly encourage participation in clinical trials comparing various drug combinations.

TREATMENT OF PATIENTS WITH RELAPSED CHRONIC LYMPHOCYTIC LEUKEMIA

The approach to reinitiating therapy for CLL patients who have relapsed after initial therapy is similar to that applied for initial therapy assessment. Patients need not receive therapy at the first sign of relapse. Rather, patients should have an indication for treatment, as discussed earlier. Patients should have repeat interphase FISH analysis of the peripheral blood or BM aspirate because patients may acquire additional cytogenetic abnormalities, most notably del(17p13.1) and TP53 mutational analysis, as their CLL becomes more advanced. The incidence of del(17p13.1) increases from 5% of patients at initial diagnosis to nearly half of heavily treated patients with advanced

CLL, and has been established as a consistent marker of poor outcomes. IGHV mutational analysis does not need to be performed if such information has been obtained previously because a patient's IGHV mutational status does not change with time. A BM should be performed if cytopenias are present to exclude other potential causes of cytopenias such as transformed lymphoma, prolonged BM toxicity from prior therapy, or development of a treatment-related myeloid neoplasia. Treatment-related myeloid neoplasia may be difficult to assess in CLL patients with extensive BM involvement but should be considered when either genomic mutations or cytogenetic aberrations present in the absence of CpG stimulation are present suggestive of this diagnosis in the setting of cytopenias. Patients with CLL should be treated according to the indications outlined in Table 76.5. Multiple novel agents have now been approved and more are in the advanced stages of development and the treatment for relapsed disease will continue to evolve with time. In general, therapy has moved away from chemoimmunotherapy to better tolerated targeted oral agents especially for patients older than 70 years of age and those with multiple comorbid conditions.

Ibrutinib for Relapsed Disease

The phase I study of ibrutinib evaluated two dose levels above where complete BTK inhibition occurred without obtaining a maximum tolerated dose. At the highest dose, toxicity was manageable, including grade 1/2 nausea, diarrhea, infections, rash, and fatigue. Activity was seen at all doses, including in nine of 16 CLL/SLL patients. A subsequent trial utilized the 420 mg daily oral dose of ibrutinib and demonstrated an ORR of 71% with an additional 20% of patients experiencing partial response with lymphocytosis (PR+L). The PR+L observed with ibrutinib in a percentage of patients does not appear to predict for inferior PFS. More importantly, the responses seen with ibrutinib were sustained and result in a PFS of 69% at 30 months. Responses to ibrutinib also tended to improve with time and after a median follow-up of 2 years, CR rates improved from 2% to 7%. Responses were also seen in patients with del17p who had an ORR of 55.9% with a median duration of response of 25 months. This compared favorably in historical comparison to either cyclin-dependent kinase inhibitors or other conventional therapies utilized in the past for patients with del17p. Patients with previously untreated CLL also appeared to benefit from ibrutinib monotherapy with an ORR of 71% and 13% PR+L. PFS at an early follow up was 96% at 2 years.

Ibrutinib was also well-tolerated in these trials and the most common side effects were diarrhea, nausea, and fatigue. A subsequent randomized study comparing ibrutinib to ofatumumab (RESONATE) in relapsed CLL confirmed the benefits of ibrutinib with improved response rate, PFS, and OS. With a median follow-up of 44 months, the median PFS was not achieved with ibrutinib and 46% of the patients were able to continue treatment. There was also a decreased incidence of grade 3 or higher AEs over time. Progressive disease resulted in discontinuation of treatment in 27% of patients on ibrutinib.

However, these studies also demonstrated a higher incidence of both minor and major bleeding episodes possibly due to a collagen-mediated platelet aggregation defect, and atrial fibrillation with ibrutinib. Ibrutinib should therefore not be used in patients on concurrent anticoagulation with warfarin and patients should be taken off ibrutinib for 3 to 7 days before and after minor or major surgical procedures respectively. Additional retrospective reports also established anti-platelet agent use as a risk factor for the increased bleeding diathesis observed in patients concurrently on ibrutinib. Given the substantial risk of bleeding with concurrent anticoagulant use with ibrutinib we generally avoid the use of anticoagulation in patients who develop atrial fibrillation after consultation with our cardio-oncology colleagues (see Chapter 158). For patients with a high risk of thrombotic or embolic events or deep venous thrombosis or pulmonary emboli, we generally utilize direct-acting oral anticoagulants (DOAC) like apixaban. We never use warfarin with ibrutinib due to an unusual and yet unexplained high frequency of subdural hematomas noted early in the development of this agent when these agents were combined. Ibrutinib use also results in an increased incidence of new or worsening hypertension requiring the addition and increased dose of antihypertensive therapy. It also increases the risk of major adverse cardiac events and ventricular arrhythmias and sudden cardiac death. Given the well-established cardiac toxicity risk with ibrutinib, we recommend a detailed cardiac evaluation prior to starting patients on ibrutinib. Patients with underlying cardiovascular disease should have formal consultation with experts familiar with these issues in the cardio-oncology field. We generally perform a baseline EKG and an echocardiogram prior to starting our patients on ibrutinib. Moreover, we also evaluate the list of their concomitant medications including antihypertensives, and maintain close communication with the primary care physician and the cardiologist throughout the treatment course.

Patients on ibrutinib experience a progressive decline in the incidence of infectious complications with continued use of ibrutinib and do not require routine anti-microbial prophylaxis. We do recommend prophylaxis with acyclovir or valacyclovir for all patients especially those with relapsed disease. There is also subjective improvements in stress, depressive symptoms, fatigue, and quality of life in patients.

Acalabrutinib for Relapsed Disease

Early data with the use of acalabrutinib for patients with relapsed CLL demonstrated very promising results. The initial phase IB/II study reported outcomes on 134 patients with relapsed and/or refractory CLL, with a median age of 66 years and median of 2 prior lines of therapy. Acalabrutinib was dosed at 100 mg twice a day and resulted in an overall response rate of 94% regardless of genomic features. With updated follow-up, the 45-month PFS was 62% (95% CI, 51% to 71%). Treatment was very well tolerated with most AEs being mild to moderate in intensity. The most common AE reported was diarrhea (52%) and headache (51%). Grade 3 or higher hypertension was reported in 7% of patients. Atrial fibrillation and major bleeding events occurred in 7% and 5% of patients respectively. The primary reason for discontinuation of treatment was progressive disease in 21% with the majority harboring BTK mutations, and AEs in 11%.

A subsequent large, phase III study of 310 patients (ASCEND) who were randomly assigned to acalabrutinib monotherapy ($n = 155$) or investigator choice therapy of idelalisib (a phosphoinositide 3-kinase inhibitor; more specifically, it blocks P110δ, the delta isoform of the enzyme phosphoinositide 3-kinase) and rituximab ($n = 119$), or bendamustine and rituximab ($n = 36$), revealed a significantly improved progression free survival advantage for acalabrutinib. Estimated 12-month PFS was 88% (95% CI, 81% to 92%) for acalabrutinib and 68% (95% CI, 59% to 75%) for investigator's choice treatment. AEs were as expected with the most common AEs in the acalabrutinib arm being neutropenia in 16%, anemia in 12%, and pneumonia in 5% of the patients. Most common AEs in patients treated with idelalisib and rituximab were neutropenia in 40%, diarrhea in 24%, and pneumonia and transaminitis in 9% of patients. Similarly, in patients treated with bendamustine and rituximab, neutropenia was the most common AE in 31% of the patients followed by anemia in 9% and constipation in 6%. Only 3% of patients who received acalabrutinib required a dose reduction compared to 24% who received idelalisib and rituximab, and 17% who received bendamustine and rituximab. Atrial fibrillation rate was 5% in the acalabrutinib arm compared to 3% in the control arm. Bleeding events were more commonly seen with the acalabrutinib arm at 26% versus 7% in the investigator's choice arm. The trial was important in establishing the superiority of acalabrutinib not just over chemoimmunotherapy but also over a PI3 kinase inhibitor in patients with relapsed and refractory disease. The toxicity profile was also favorable, and these results led to the approval for acalabrutinib in the relapsed/refractory setting.

Since treatment with ibrutinib or acalabrutinib does not result in CRs in the majority of patients, at this time it is recommended that treatment be continued indefinitely until disease progression or unacceptable toxicity, since discontinuation in heavily pre-treated patients often results in rapid disease progression. Development of resistance has been rare but whole exome sequencing has identified a cysteine-to-serine mutation in BTK at the binding site of ibrutinib and acalabrutinib, and distinct mutations in PLCγ2. Functional analysis revealed that the C481S mutation of BTK results in a protein that is only reversibly inhibited by ibrutinib. The R665W and L845F mutations in PLCγ2 are both potentially gain-of-function mutations that lead to autonomous B-cell-receptor activity. Gate-keeper mutations in the (481I or 481 M) are rarely noted with irreversible BTKi but may be observed more commonly as reversible BTKi are introduced into clinical practice.

Venetoclax in Relapsed Chronic Lymphocytic Leukemia

The utility of venetoclax was initially reported in the initial phase I/II clinical trial of 158 patients with predominantly relapsed, refractory disease. Use of venetoclax was associated with an ORR of 77% and 2-year PFS was 54%. Encouraging activity was also observed in patients who had failed prior kinase inhibitor-based treatments. Initial issues with tumor lysis syndrome were overcome with a graduated dose ramp up over a period of 4 weeks.

In the landmark open label, phase III MURANO trial of 389 patients, venetoclax treatment for 24 months was combined with rituximab for the first 6 months and compared to standard doses of bendamustine and rituximab for 6 months. With a median follow-up of approximately 2 years, PFS was significantly higher in patients treated with venetoclax and rituximab as compared to bendamustine and rituximab (84.9% vs. 36.3%, respectively HR 0.17; 95% CI, 0.11 to 0.25; $P < .001$). The improved outcome was seen across all subgroups of patients. Most common AE was neutropenia in 60.8% of patients in the venetoclax and rituximab group and 44.1% of patients in the bendamustine and rituximab group. Despite the higher incidence of neutropenia with venetoclax, the incidence of grade 3 to 4 febrile neutropenia and grade 3 or 4 infections were lower in the venetoclax and rituximab group. Clinical tumor lysis syndrome was only seen in one patient and was mitigated by the graduated ramp-up approach.

Importantly, patients who have failed to achieve a response to venetoclax had dismal outcomes with a median PFS of 5.4 months. Similarly, patients treated with prior kinase inhibitors, and with bulky disease and lymph nodes of ≥10 cm, appear to have a lower response rate. In addition, the addition of rituximab appeared to significantly improve the rate of CR.

Subsequent pooled efficacy analysis of four early-phase clinical trials of venetoclax including 436 patients in the relapsed and refractory setting demonstrated excellent efficacy of venetoclax with an ORR of 75% including a 22% CR rate. Undetectable MRD in the blood and marrow was achieved in 27% and 16% of patients respectively. Estimated median PFS was 30 months. As predicted, duration of response was longer in patients achieving undetectable MRD. PFS, but not response rate, was also inferior in patients with del17p or aTP53 mutation. A later pooled safety analysis of 350 patients who had received a median of 3 prior therapies, including kinase inhibitors in 42%, demonstrated manageable toxicity with the most common AEs being diarrhea (41%), neutropenia (40%), nausea (39%), anemia (31%), fatigue (28%), and upper respiratory tract infection (25%). The most common grade 3/4 AEs were neutropenia (37%), anemia (17%), and thrombocytopenia (14%). The incidence of clinical tumor lysis syndrome was nonexistent with the current graduated ramp-up of venetoclax dosing and laboratory evidence of tumor lysis syndrome was observed in less than 2% of patients. These studies not only resulted in the approval of venetoclax and rituximab for patients with relapsed/refractory CLL, but also established its efficacy and the safety of the graduated ramp-up dosing approach.

PI3-Kinase Inhibitors

Idelalisib is an orally bioavailable, isoform specific, PI3-kinase-δ inhibitor that, at therapeutic levels obtained in patients, does not inhibit other isoforms of PI3-kinase. Genetic mouse models knocking out PI3-kinase delta demonstrate predominantly a B-cell defect, absent B1 lymphocytes, and disrupted BCR signaling. Preclinical studies by our group and later confirmed by others demonstrated that idelalisib promotes the apoptosis of CLL cells via a PI3-kinase-δ pathway and inhibits signals from the microenvironment that protects CLL cells from apoptosis. Based in part on these data, a phase I study in healthy volunteers showed this agent to be well tolerated, and subsequently a large phase I study in NHL, CLL, multiple myeloma, and AML was undertaken. Idelalisib was active at all dose levels tested, with the dose-limiting toxicity being reversible transaminitis that generally occurred during the first 2 months of therapy in approximately 5% to 20% of patients, depending on histology. Although patients with NHL experienced a higher incidence of transaminitis, the cause of which is poorly understood, the incidence of transaminitis was less than 5% in CLL patients. In a phase I trial of 54 patients, with relapsed/refractory high-risk CLL patients, idelalisib resulted in an ORR of 72% (including PR+L). The median PFS was 15.8 months. Therapy was generally well tolerated with the most commonly observed Grade ≥3 AEs being pneumonia in 20%, neutropenic fever in 11%, and diarrhea in 6% of the patients. Subsequent studies have been undertaken with idelalisib combining it with rituximab, ofatumumab, obinutuzumab, and bendamustine/rituximab, showing that combination therapy with idelalisib is feasible. The combination of idelalisib and rituximab was also compared to rituximab and placebo in a phase III trial and resulted in an ORR of 81% versus 13% and PFS at 1 year in excess of 90% versus 5.5 months in the rituximab and placebo arm respectively. Serious toxicities observed with idelalisib were similar to ones observed with the single agent. Based on these results, idelalisib was approved in combination with rituximab for the treatment of patients with relapsed CLL. However, its use has been limited given the clinical activity and excellent tolerability of BTK inhibitors, and the serious immune mediated toxicities observed with the use of idelalisib including transaminitis, colitis, pneumonitis, and increased incidence of infectious complications. Colitis can also be a delayed complication and can be severe and manifest itself 4 to 6 months after starting treatment. Pneumonitis can also be particularly difficult to distinguish from infectious issues commonly seen in these patients. CMV reactivation also needs to be monitored closely. Since these toxicities can be particularly severe and potentially life-threatening in patients with previously untreated disease, we do not recommend the use of idelalisib in patients with previously untreated CLL. In addition, dose reductions and dose interruptions can actually result in improved tolerability, compliance, and PFS.

Duvelisib is another agent in this class that inhibits both PI3-kinase-δ and γ, an isoform expressed in T cells, myeloid cells, and other cell types. The initial phase I study of duvelisib in patients with relapsed refractory CLL established a maximum tolerated dose of 75 mg twice a day. However, the study also demonstrated a sustained maximum pharmacodynamic effect at a dose of 25 mg twice daily. The 55 patients with relapsed/refractory CLL/SLL that were treated had an ORR of 56% with a median progression free survival of 15.7 months and median duration of response of 21 months. Based on this study, a randomized phase III clinical trial was conducted in 319 patients with relapsed/refractory CLL/SLL who had received two or more prior therapies. Patients were randomized to duvelisib at 25 mg twice a day or ofatumumab. ORR was better with duvelisib as compared with ofatumumab (73.8% vs. 45.3%, $P < .0001$), with almost all responses being partial (72.5% duvelisib and 44.7% ofatumumab) and this translated into an improved median progression free survival as compared to ofatumumab (13.3 vs. 9.9 months; hazard ratio, 0.52; $P < .0001$). Outcomes for duvelisib were also better among del(17p) and/or TP53-mutated patients as compared to ofatumumab (median PFS of 12.7 vs. 9.0 months; hazard ratio, 0.40; $P = .0002$).

Most common AEs observed with duvelisib included neutropenia, anemia, and infectious complications. This included infections with opportunistic organisms. In this and other studies of duvelisib, immune mediated toxicities such as transaminitis, hepatitis, diarrhea, colitis, pneumonitis, and rash were also observed. This occurred in almost half of patients treated with duvelisib. As with idelalisib, this occurred secondary to increased CD8 positive effector cell infiltration of the organ experiencing the AE. This resulted in a significant proportion of patients requiring dose reductions and discontinuations. Despite the significant toxicity seen with the use of PI3-kinase inhibitors, they do have an important role to play in the management of patients with relapsed refractory CLL/SLL who would not ordinarily be considered candidates for BTK inhibitors or BCL-2 antagonists, either because of comorbid conditions or underlying organ dysfunction. They also appear to have some activity in patients who have failed prior BTK inhibitors although remission with these agents is relatively short. We do recommend close monitoring of patients on these agents especially for immune mediated AEs, and recommend employing dose reductions and drug holds in the setting of AEs. In particular, we caution continuing these agents when patients develop pneumonitis or colitis as sometimes significant morbidity can follow.

Role of Novel Agents in the Management of Patients With Del(17p13.1)

Conventional chemotherapy has limited benefit in the initial treatment of patients with del(17p13.1) and median PFS is in the range of 11 to 14 months. Over time del(17p13.1) and/or TP53 mutations have consistently emerged as reliable prognostic markers for inferior outcomes. While BTK inhibitors have significantly improved outcomes for patients with CLL, the outcome for patients with del(17p13.1) remains inferior to patients without this particular deletion or mutation. Ibrutinib's initial approval for patients with del(17p13.1) was based on limited data which demonstrated overall responses of up to 97% in this high-risk group of patients. These responses were rapid and improved over time and resulted in a progression free survival at 12 months of 82%. Given the significant improvement in outcomes in this patient cohort compared to historic controls, ibrutinib was approved for this indication across all lines of treatment. A subsequent integrated analysis of 230 patients with relapsed and refractory del(17p13.1) patients demonstrated an overall response rate of 85% with a 30-month progression-free and OS rates were 57% (95% CI 50 to 64) and 69% (95% CI 61 to 75), respectively. Similarly, patients treated with acalabrutinib in the phase I clinical trial demonstrated an overall response rate of 100% with PR in 89% and PR+lymphocytosis in 11% of patients. These results were similar to those observed with ibrutinib and response appears to be sustained over time. Venetoclax was also initially evaluated in 107 patients with del17p in the relapsed and refractory setting. Despite initial issues with tumor lysis syndrome, treatment with venetoclax was very effective and resulted in a 12-month PFS of 72%. Most common AEs were gastrointestinal including diarrhea, nausea, and cytopenias. Based on these results, and the comparison with historical data, chemoimmunotherapy-based regimens have limited use in the management of patients with del17p either in the untreated setting or in patients with relapsed/refractory disease. The choice of novel agent should be based on patient preferences, comorbid conditions, and clinical scenario.

Sequencing of Therapy and Management of Patients Relapsing After Novel Therapies

Early studies with ibrutinib demonstrated excellent tolerability and slow disease progression of patients who had to discontinue treatment because of AEs. This amounted to approximately 16% of patients over 6 years of follow-up in the RESONATE trial. However, real-world evidence suggests intolerance-related discontinuation with ibrutinib of approximately 30% to 50% over time. A substantial percentage of these patients who discontinue ibrutinib because of AEs do not require therapy immediately and can be monitored with active surveillance. However, in the event of progressive disease and the need for subsequent therapy acalabrutinib can be employed and has a demonstrated overall response rate of 76% with a 2-year progression free survival of 76% in these patients. In addition, the use of acalabrutinib resulted in recurrence of ibrutinib-attributable AEs in only a small minority. The vast majority of patients had either complete resolution or decrease in the severity of the AEs that resulted in the discontinuation of ibrutinib.

Management of patients in the relapsed setting in the recent chemotherapy free era can be challenging and dependent on the choice of first-line therapy. Patients progressing on BTK inhibitors can experience rapid tumor flare upon discontinuation for progressive disease, and hence we do not recommend abrupt discontinuation of these agents. BTK inhibitors should be overlapped with next-line agents as overlapping therapy, or alternatively bridging therapy such as steroids can be utilized for this purpose. In addition, it is important to rule out Richter transformation in the appropriate clinical situation. We also recommend repeat evaluation by FISH and karyotype to assess for clonal evolution along with testing for BTK and PLCγ2 mutations. In the absence of good quality clinical trial data, management of these patients progressing on BTK inhibitors is derived from real-world experiences which demonstrate that in patients progressing after prior BTK inhibitors, venetoclax-based treatment appears to have the best outcomes as compared to alternative treatments including PI3K inhibitors and chemoimmunotherapy. Similarly, patients progressing on venetoclax-based treatments should be tested for clonal evolution and BCL-2 resistance mutations. Venetoclax monotherapy in the setting of prior BTK failure resulted in an overall response rate of 65% in one study with a PFS and OS of 75% and 91% at 1 year respectively. This also allows an opportunity for deep MRD undetectable responses and fixed-duration therapy and is the preferred treatment modality in this setting. PI3K inhibitors have modest activity in this setting.

For patients who discontinue venetoclax-based treatment as a predefined option, retreatment with venetoclax either as a single agent or in combination with rituximab results in excellent outcomes. However, this retreatment approach is best suited for patients who experience a prolonged treatment free interval after discontinuation of venetoclax. Ibrutinib has also been shown to be effective in this setting with promising responses and prolonged disease control. For BTK inhibitor-naïve patients who progress after venetoclax-based treatment, the ORR to venetoclax varies from 84% to 100% and drops to around 54% with previous BTK inhibitor exposure. We therefore recommend that patients progressing after venetoclax-based therapy should be considered for retreatment with venetoclax especially if they have experienced a prolonged remission and treatment-free interval with initial venetoclax-based treatment. For patients who have previously failed BTK inhibitors or with demonstrable BTK resistance mutations, and demonstrate progression after venetoclax, BTK inhibitors should not be utilized, and patients should be considered for participation in clinical trials of alternative treatments, non-covalent BTK inhibitor, bispecific T-cell engagers (BiTEs), chimeric antigen receptor T-cell (CAR-T), and allogeneic hematopoietic stem cell transplantation (HSCT) in the appropriate setting. For patients progressing after prior chemoimmunotherapy use, we generally recommend the use of BTK inhibitors followed by venetoclax post relapse from BTK inhibitors.

Allogeneic HSC transplantation or CAR-T-cell therapy should also be considered for patients progressing after two prior lines of treatment with novel therapies or who demonstrate lack of response to novel agents. The prior use of ibrutinib does not appear to impact transplant-related outcomes. Noncovalent and reversible BTKi inhibitors are currently being tested in patients with documented resistant BTK C481S mutation. Early results with LOXO-305 demonstrated an impressive ORR of 57% with improvement in the depth of response over time in this high-risk patient population. The drug was also extremely well tolerated with a small proportion of patients experiencing fatigue and diarrhea. Similar promising early results and excellent tolerability has been shown in patients with ARQ531.

Other Emerging Therapeutic Modalities for Chronic Lymphocytic Leukemia

Several other promising therapeutics are in late phase II/III clinical trials for CLL. Those with documented activity in this disease that have potential for approval for use in CLL in the near future are described here.

Zanubrutinib is a potent and selective BTK inhibitor which utilizes the same C481 binding domain as ibrutinib and acalabrutinib. It is already approved for the treatment of patients with mantle cell lymphoma in the relapsed setting (see Chapter 86). It is also being compared to ibrutinib in a head-to-head, noninferiority, clinical trial in the relapsed and refractory setting. While its advantages over existing BTK inhibitors remain to be elucidated, its use does offer the potential advantage of a lower incidence of bleeding and cardiovascular toxicity, and the flexibility of twice a day or once a day dosing. Moreover, its bioavailability does not appear to be impacted by the use of concurrent proton pump inhibitors which can impact acalabrutinib use.

Umbralisib is a PI3K-δ and casein kinase-1 epsilon (CK1ε) inhibitor that has demonstrated promising activity in patients with CLL. It is currently approved for use in patients with marginal zone lymphoma and follicular lymphoma (see Chapters 82 and 83). In early results of 51 patients with relapsed/refractory CLL, 44 of whom were intolerant to BTK inhibitors and seven of whom were intolerant to PI3 kinase inhibitors, the median PFS was 23.5 months. Treatment was well-tolerated and most common AEs were neutropenia (18%), thrombocytopenia (12%), pneumonia (12%), diarrhea (8%). Treatment-related discontinuation occurred in 12% of patients treated with umbralisib. Combination of this drug with a new anti-CD20 monoclonal antibody ublituximab also demonstrated good tolerability with modest activity and an ORR of 46% with 17% CR in patients with relapsed/refractory CLL and other indolent lymphomas. Similar to the issue with the comparison of ibrutinib with alternative BTK inhibitors, while umbralisib appears to have a better toxicity profile as compared to other PI3 kinase inhibitors, head-to-head comparative data is currently lacking.

Multiple exciting agents are also in development, including BiTEs, various CAR-Ts, and other immunomodulatory agents portending an excellent prognosis for our patients.

Chimeric Antigen Receptor T-Cell Therapy

A major development over the last few years has been the approval of ex vivo transfected T cells with chimeric T-cell receptors bearing both CD3 and a B-cell–specific antigen (most often CD19) for various aggressive and indolent lymphoid malignancies. Trials for patients with CLL are currently ongoing but early results from studies evaluating patients with relapsed CLL following BTK inhibitors demonstrated an ORR of 87% with a CR and u-mRD rate of 47% in patients treated with lisocabtagene maraleucel. The use of ibrutinib in the peri-CAR-T phase appears to result in a higher ORR and improves ex vivo T-cell expansion. With improving understanding and management of toxicities, outcomes are continually improving and this treatment option has the potential to be a definitive treatment option for a number of patients with relapsed CLL. For patients progressing on BTK or BCL2 inhibitors, we recommend consultation with a CAR-T center to consider enrollment on a clinical trial.

Hematopoietic Stem Cell Transplantation

For many years, autologous and allogeneic HSCTs were generally used for treatment of CLL late in the course of the disease. Although autologous HSCT has been used historically as a treatment for CLL, nonmyeloablative allogeneic SCT is the preferred modality for most patients requiring a HSCT unless a suitable allogeneic donor is not available. Autologous SCT is no longer utilized in CLL because of a lack of a survival advantage, only modest benefit in PFS, and a high risk of treatment related mortality with this modality. With increasing recognition of poor prognostic factors, early HSCT has been recommended for some patients, including patients with a complex karyotype and who demonstrated early relapse after kinase inhibitor-based treatments. However, with the increasing use of venetoclax, availability of CAR-T-cell and additional therapeutic options, the optimal timing of HSCT is further open to debate, and the utility of HSCT as a salvage option for patients with CLL has declined considerably over the last decade. Nevertheless, we do recommend referral to a transplant center for patients exhibiting early relapse on kinase inhibitor-based therapies, or who fail to demonstrate response to venetoclax. These patients should ideally undergo HLA typing and identification of a suitable donor.

Initial use of TBI-containing myeloablative regimens demonstrated a lower transplant-related mortality (TRM) of 17% at 100 days compared to 57% in patients who received busulfan and cyclophosphamide (BuCy)-based conditioning regimen. Multiple retrospective registry evaluations continued to demonstrate unacceptably high TRM of greater than 30% and 5-year OS of less than 50% with these approaches. These dismal outcomes persisted despite the use of related and/or unrelated donor sources. Because of the lower toxicity of the TBI-based regimens, BuCy-based myeloablative conditioning regimens should not be routinely used in patients undergoing HSCT for relapsed CLL.

The goal of HSCT is to harness the GVL effect of allogeneic HSCT for patients with CLL while reducing TRM from acute graft-versus-host-disease (GVHD), acute infection, and organ toxicity associated with myeloablative conditioning. EBMT retrospectively examined 77 CLL patients who received a variety of nonmyeloablative conditioning regimens, followed by allogeneic HSCT. The 1-year TRM was 18%, and the 2-year probability of relapse was 31%. Two-year DFS and OS were 56% and 72%, respectively. Nineteen patients received donor lymphocyte infusions (DLIs) for relapse or incomplete donor chimerism, but only seven responded to DLI (37%). Unfortunately, this study was complicated by the heterogeneity of conditioning regimens and the use of antithymocyte globulin (ATG) or Campath-1H for T-cell depletion of the grafts in 40% of patients. A retrospective analysis of 73 CLL patients who underwent nonmyeloablative SCT and 82 patients who underwent myeloablative allogeneic SCT showed that the TRM was significantly reduced in the former group, with a hazard ratio of 0.4; however, there was no difference in EFS or OS between the two groups. Other studies employing low-dose TBI with fludarabine, or fludarabine with melphalan and alemtuzumab, demonstrated 2-year TRM of 22% to 27% OS of around 50%.

Given the decline in the utility of allogeneic HSCT in the era of novel therapies, data on optimal utilization of this treatment strategy is limited. In a recent retrospective series of 108 high-risk patients, allogeneic HSCT demonstrated a 3-year OS of 87% (95% CI, 68%, 95%), PFS of 72% (95% CI, 52%, 85%), cumulative incidence of NRM of 7% (95% CI, 1%, 19%), and cumulative incidence of relapse of 21% (95% CI, 8%, 38%). Of the 30 patients included in this cohort with a history of prior treatment with novel agents, transplant-related outcomes tended to be better as compared to patients treated with chemoimmunotherapy-based approaches but this was not statistically significant. In addition, the use of non-fludarabine and busulfan-containing regimens and presence of Richter transformation was associated with worse outcomes.

Management of Chronic Lymphocytic Leukemia in Specialized Centers

Given the recent advent of prognostic markers and treatment options in CLL, a study that examined the impact of physician expertise on patient outcomes in CLL has shown that disease-specific expertise made significant differences in outcomes across all aspects of patient care from prognostic evaluation to choice of therapy. These findings suggest that the expertise of the physician caring for the patient with CLL/SLL is an independent prognostic variable that may not be related to the number of patients he or she manages. We therefore recommend that all patients with newly diagnosed CLL/SLL should be managed in consultation with a CLL expert at a tertiary care center with access to the most recent molecular diagnostic tools.

SPECIAL CLINICAL SCENARIOS IN CHRONIC LYMPHOCYTIC LEUKEMIA

Young Patients (Younger Than 50 Years of Age) With Chronic Lymphocytic Leukemia

As mentioned previously, CLL is a disease of elderly adults, with only 10% of patients being younger than the age of 50 years at diagnosis. Although CLL patients live for a prolonged period of time, young patients without comorbid illnesses have a great potential to have their lives significantly shortened by the disease, irrespective of their cytogenetic abnormalities. Additionally, stress associated with job performance, insurance coverage maintenance, and disease-related symptoms are most significant in this age group. Special attention to psychosocial issues related to CLL should occur early in the course of the disease to allow patients to maintain or resume their normal lifestyles as soon as possible. Similarly, this group faces unique challenges concerning the choice of novel therapies. While kinase inhibitor-based treatments have the potential to control disease for a prolonged period of time, data beyond 10 years is limited. It also forces the patient to take a treatment indefinitely until progressive disease or intolerable toxicity. Similarly, long-term outcomes data after time-limited venetoclax treatment is lacking. In addition, if the young patient has mutated IGHV then treatment with FCR chemoimmunotherapy can be a consideration albeit at a higher cost of toxicity- and risk of treatment-related myeloid malignancies. Nevertheless, given the advent of multiple promising therapeutic options with a possibility of durable remissions, our approach is generally not to empirically pursue HLA typing or examine transplant options before the development of symptomatic disease. When therapy is initiated for this group of patients, aggressive intervention to promote prolonged remission duration is always compared to prolonged disease control state with the use of kinase inhibitors. HSCT and/or CAR-T-cell therapy is generally considered for patients in this age group who have high-risk cytogenetic abnormalities in second remission and for all patients who do not respond to initial novel agent-based therapy.

Richter Syndrome

Richter syndrome (RS), the development of high-grade lymphoma in patients with CLL, was described by Maurice Richter in 1928. Over the years, the classification of RS has expanded to include lymphoid malignancies such as Hodgkin disease, lymphoblastic lymphoma, PLL, and hairy cell leukemia (see Fig. 76.4A–C). Incidence estimates range from 2.8% to 10.7%. Studies have suggested that the development of RS may be related to the evolution of an abnormal clone unrelated to the underlying CLL clone (clonally unrelated ~30%) or arise from the underlying CLL (clonally—related ~70%). Clearly identifiable risk factors for the development of RS are lacking, and its development has been shown to be independent of disease stage, duration of disease, type of therapy, or response to therapy. However, the presence of diffuse lymphomatous involvement, advanced Rai stage, IGHV-unmutated disease, ZAP-70 expression, high LDH, del(17p13.1), high serum β_2M levels, and NOTCH1, TP53, CDKN2, and MYC gene mutations may predict the development of RS. However, these genetic abnormalities can be varied in patients progressing with RS while on treatment with novel therapies. It is notable that patients developing Richter transformation very often do not have mutations in BTK or PLCG2 after ibrutinib therapy. While there were initial concerns that treatment with novel agents might increase the incidence of RS, this has been refuted with longer-term follow-up from large, prospective clinical trials and the incidence appears to be similar to that with the use of chemoimmunotherapy. RS is characterized by sudden onset of B symptoms (fever, night sweats, weight loss) and rapidly progressive lymphadenopathy at any anatomic site. Rarely, the lymphomatous clone may arise from the bone or an extranodal site. Laboratory abnormalities including anemia, neutropenia, and thrombocytopenia may be due to large-cell transformation in the BM. A rapid increase in the serum LDH is seen in the majority of patients. The diagnosis is generally made after examining the histology of a rapidly enlarging lymph node, which typically reveals large-cell lymphoma. The most common histologic subtype of RS (~90%) is diffuse large B-cell lymphoma (DLBCL) and Hodgkin lymphoma is seen in approximately 10% of cases. PET scans can be helpful to localize the most hypermetabolic node for biopsy and also have a high specificity if the SUV max is ≥10. However, every attempt should be made to confirm the diagnosis through biopsy of the most FDG avid lymph node. Historically, outcomes for clonally related RS is poor, with most patients exhibiting chemorefractory disease. Clonally unrelated RS variants are treated similar to de novo diffuse large B-cell lymphoma and tend to have slightly better outcomes. Historically, RS has been treated with regimens similar to those used for the treatment of large-cell lymphomas involving multiple agents such as R-CHOP, OFAR, and R-EPOCH, etc. Outcomes remain dismal with any treatment modality with the best response rates of around 50% and median OS of less than 18 months seen with the use of venetoclax in combination with R-EPOCH, unless the patient can be salvaged with an allogeneic HSCT. This particular regimen is associated with substantial cytopenias but almost doubles the dismal survival seen with prior therapeutic modalities. Long-term remissions and survival have been reported in a few patients after allogeneic HSCT, but this approach is associated with a high TRM. When Richter transformation occurs, treatment on a clinical trial and consolidation with allogeneic HSCT is the preferred treatment. Newer treatments including kinase inhibitor combinations and checkpoint inhibitors have been used in small series with modest success.

Similar to RS, prolymphocytic transformation (PT) occurs in fewer than 10% of patients with CLL. PT is characterized by the appearance of large, immature prolymphocytes in the peripheral blood, which make up greater than 55% of the peripheral circulating malignant lymphoid cells. These patients may be older with advanced disease and have more pronounced lymphadenopathy and splenomegaly. PT is associated with a poor outcome, with limited survival beyond 1 year. These patients often have del(17p13.1) but do appear to respond to many of the novel therapies currently utilized for the treatment of CLL. Allogeneic HSCT or CART cell therapy may also be used as a potentially curative therapeutic option if targeted agents become ineffective.

Hodgkin lymphoma can also manifest as a form of Richter and may have a better outcome provided patients are treated appropriately. Identification of this diagnosis can sometimes be challenging due to its identification in BM, lower SUV readings on PET scan, and also more insidious onset as compared to DLBCL presentation of RS. Hodgkin lymphoma in the setting of CLL can be treated as de novo disease with some individuals attaining long-term remissions with ABVD or similar regimens (see Chapter 80). Unlike DLBCL, transformation of CLL to RS where reduced intensity allogeneic HSCT is recommended, we generally do not pursue this for individuals with Hodgkin lymphoma transformation.

Secondary Malignancies in Chronic Lymphocytic Leukemia

CLL is associated with an increased risk of secondary malignancies. These include not only hematologic malignancies such as MDS and AML associated with the use of chemotherapeutic agents but also solid tumors such as Kaposi sarcoma, malignant melanoma, and laryngeal and lung cancers. The increased incidence of secondary malignancies may be attributable to multiple reasons, including the immune dysfunction associated with CLL, the frequent infectious complications, the carcinogenic side effects of the various chemotherapeutic agents, and the increased and close medical surveillance that patients with CLL receive from trained oncologists. Hopefully, with the declining use of chemoimmunotherapeutic regimens the incidence of treatment-related myeloid malignancies will decline over time.

Hypersensitivity in Chronic Lymphocytic Leukemia to Mosquitoes and Insect Bites and Treatment

Patients with CLL commonly exhibit an exaggerated cutaneous response to insect bites. This was first reported in 1965 by Robert Weed, who documented a hypersensitivity reaction to insect bites in eight of 97 patients with CLL over a 13-year period. The reaction is characterized histologically by the presence of a dermal infiltrate composed of a mixed population of T and B cells, eosinophils, and eosinophilic granule protein. The extent of eosinophilic degranulation may also correlate with the severity of symptoms. Clinically, these patients present with recurrent, painful, bullous eruptions that may be traced to an insect bite in some instances. In limited cases, we have also observed that CLL patients have hypersensitivity to bed bugs, and this should be considered in the differential diagnosis. Identification and avoidance of known triggers may be useful in some cases, but most patients are unable to identify the inciting exposure. Treatment with a short course of steroids is usually effective, but these patients frequently relapse and may require multiple courses of therapy. Dapsone and chlorambucil may also be useful in severe, recurrent cases.

Other cutaneous conditions are also common in CLL patients, with up to 45% reporting some form of skin involvement. These include petechial, purpura, or ecchymotic lesions related to thrombocytopenia; infectious eruptions such as herpes simplex and zoster; and direct leukemic involvement in fewer than 10% of all patients with advanced disease.

INFECTIONS IN PATIENTS WITH CHRONIC LYMPHOCYTIC LEUKEMIA

Infectious complications remain the leading cause of morbidity and mortality in patients with CLL (see Chapter 94). The incidence of infectious complications has been estimated to be as high as 80% with a mortality rate of approximately 60%. Various factors contribute to the increased incidence of infectious complications in CLL, the most important being progressive disease affecting host immunity through an impaired antibody response and hypogammaglobulinemia; weakened host cellular immune responses, including impaired macrophage function; a decrease in T-regulatory cells; and, finally, the acquired defects after immunosuppressive chemotherapy.

Recent studies have examined predictors of severe infections in patients with CLL. In their retrospective analysis of infection-related mortality in 280 patients, advanced age, clinical stage B or C disease, unmutated IGHV, and positive CD38 status have been identified as independent predictors of both shorter time to first infection and infection-related mortality. Other risk factors that may also have an impact on development of infections include type of initial therapy and development of renal insufficiency.

Historically, sinopulmonary infections from encapsulated bacteria such as *Streptococcus pneumoniae* and *Haemophilus influenzae* have been the most common cause of infectious complications in patients with CLL. With the recent use of more potent cytotoxic chemotherapy and the resultant profound myelosuppression, an increased frequency of severe pulmonary infections, bacteremia, and gram-negative infections has been reported. Infections caused by atypical organisms such as *Listeria monocytogenes, Nocardia* spp., *Mycobacterium* spp., and *Neisseria meningitidis* are relatively infrequent in patients who receive conventional chemotherapy. Treatment for presumed infection should be initiated empirically in CLL patients who develop fever because fever in CLL patients usually indicates an active infection. Therapy should be tailored to the particular organ involved and the sensitivity of the organism. Prophylactic antibiotics can be initiated for debilitated patients with high-risk disease and significant immune dysfunction.

Viral infections are also commonly encountered in CLL patients (see Fig. 76.3D and E). Herpesvirus infections are especially common in patients treated with nucleoside analogs and alemtuzumab. Chronic, indolent oropharyngeal and circumoral herpes simplex virus (HSV) outbreaks are more frequent than aggressive, disseminated visceral disease. Reactivation of Epstein-Barr virus (EBV) has been implicated in some cases of Richter transformation. Other viruses may cause severe systemic disease in patients with CLL. Varicella zoster virus (VZV) can cause herpes zoster, herpetic neuralgia, and rarely meningoencephalitis; parvovirus B19 can cause severe polyarthritis and pure RBC aplasia; and JC polyoma virus has been implicated in the development of progressive multifocal leukoencephalopathy. Management of these infections depends on early recognition of disseminated viral disease, timely initiation of antiviral therapy in cases of HSV and EBV, and a low threshold for the introduction of prophylactic acyclovir and supportive therapy. All patients should be provided instruction to identify the signs and symptoms of herpes virus infection at the time of diagnosis of CLL.

Fungal infections are not typically observed in CLL patients in the absence of treatment with corticosteroids or other immunosuppressive therapy for autoimmune complications arising from CLL. Cryptococcal meningitis, pneumonia, and fungemia are well-recognized events in patients with CLL and are associated with significant morbidity and mortality. More cases of *Pneumocystis. jirovecii* pneumonia, systemic candidiasis, and aspergillosis were reported with the advent of combination nucleoside analog therapy with steroids. However, while these issues are still seen in patients treated with novel agents their incidence is much lower. Treatment of the infection is dictated by the identification of the particular organism. Trimethoprim–sulfamethoxazole is routinely used as effective prophylaxis against *P. jirovecii* infections, especially during and immediately after the use of nucleoside analogs. Fungal prophylaxis with posaconazole may also be used during protracted therapy with high-dose steroids to avoid invasive aspergillosis.

Prophylactic Strategies for Infections

Routine use of prophylactic antibiotics is generally not used for CLL despite the higher frequency of infections observed in patients with this disease. Early recognition of signs and symptoms of infection and prompt initiation of empiric broad-spectrum antibiotics is probably a more feasible and cost-effective approach. When chemoimmunotherapy is used that includes a nucleoside analog, prophylaxis for herpes simplex and varicella zoster should be used, particularly in older patients. Trimethoprim–sulfamethoxazole (or other alternative *P. jirovecii* pneumonia prophylaxis) should also be administered in this setting. Fortunately, kinase inhibitors result in continued decline in the incidence of infectious complications with ongoing therapy, primarily as a result of better disease control, and routine prophylactic antibiotics are either not required or can be weaned off in the majority of patients. We do however use acyclovir prophylaxis for all our patients on BTK and BCL2 inhibitors and both acyclovir and trimethoprim—sulfamethoxazole for patients on PI3K inhibitors.

Hypogammaglobulinemia is virtually always present in advanced CLL, and several studies have examined whether intravenous immunoglobulin (IVIG) replacement therapy can reduce the incidence and severity of infectious complications. Patients receiving IVIG in a double-blind, placebo-controlled trial experienced significantly fewer bacterial infections than the placebo group. The therapy was well tolerated with few adverse reactions, but there was no observed benefit in terms of preventing viral or fungal infections. However, other studies have shown an almost 50% reduction in the number of serious infections per year with IVIG infusions. Limited data support the use of IVIG at a higher dose of 600 mg/kg every 4 weeks to reduce the number and severity of respiratory infections. However, the prohibitive cost of IVIG therapy and the fact that it has not been shown to prolong survival argues against its empiric use in all patients. IVIG should be used judiciously and reserved for patients with advanced disease and recurrent infections. The usual dose used is 200 to 400 mg/kg every 4 to 6 weeks as needed, with the aim of keeping the trough serum IgG concentration greater than 500 mg/dL.

This is something our group routinely implements for refractory patients or those who have more than two infections requiring hospitalization in 1 year.

Among the strategies for preventing infections in this patient population is immunization. CLL patients, however, typically respond poorly to pneumococcal and influenza vaccines. Advanced age, advanced disease stage, hypogammaglobulinemia, and low levels of soluble CD23 influence the rate of responses to immunizations. Soluble CD23, a degradation product of membrane-bound CD23, is involved in several aspects of B-cell activation and proliferation and has a synergistic effect on histamine release. Histamine has a direct inhibitory effect on immunoglobulin production by B cells in vitro via histamine type-2 (H2) receptors and acts as an immune regulatory factor that can be modulated by H2-receptor antagonists. Thus responses to vaccines may be further enhanced by adjuvant treatment with H2 blockers. Studies have shown that response to protein-conjugated vaccines may be enhanced by ranitidine in CLL patients to as much as 90% compared with 43% in the control group. Unfortunately, this response is not seen with polysaccharide vaccines. Other studies have indicated that protein-conjugated vaccines may be more immunogenic, as shown by a more significant immune response to *H. influenzae* type b conjugate vaccine than to plain polysaccharide antigen. In light of the paucity of data on an appropriate immunization schedule, we suggest a modified immunization plan based on the recommendations of the Advisory Committee on Immunization Practices. This includes use of Prevnar-13 for pneumococcal prophylaxis and avoiding live vaccines, including the live attenuated VZV. The newer recombinant varicella vaccine is safe for use and modestly effective.

Growth factors such as G-CSF or granulocyte–macrophage colony-stimulating factor (GM-CSF) can be used prophylactically in high-risk, severely neutropenic patients to shorten the duration and severity of neutropenia.

AUTOIMMUNE COMPLICATIONS OF CHRONIC LYMPHOCYTIC LEUKEMIA

Patients with CLL have a greater predisposition to develop autoimmune hematologic complications, including AIHA, idiopathic thrombocytopenia purpura (ITP), and pure RBC aplasia. AIHA occurs in up to 37% of CLL patients at some time during the course of their disease. A small proportion (10% to 15%) of patients may present with AIHA at diagnosis (see Chapter 47). AIHA can have a varied presentation, with patients developing signs of anemia, including weakness, lethargy, dyspnea on exertion, and dizziness over a period of months. Examination may reveal pallor, jaundice, hepatosplenomegaly, and lymphadenopathy. Hemolysis can cause mild to moderate indirect hyperbilirubinemia, elevated LDH levels, and hemoglobinuria. The direct antiglobulin Coombs test result is positive in up to 74% of patients with CLL, but not all patients develop hemolysis. Most of the antibodies produced are warm reactive, but patients can occasionally present with cold agglutination syndrome. The antibodies are mostly polyclonal and usually a product of normal B cells rather than the leukemic clone.

In contrast to the high frequency of AIHA in CLL, ITP or ITP and AIHA, or Evans syndrome, occurs less frequently in CLL. These events can occur throughout the entire course of CLL and are much more difficult to diagnose because of the absence of multiple implicating laboratory features as seen with AIHA. Given the small number of patients with AIHA, there are no data from controlled trials to guide the management of AIHA. Glucocorticoids have been used since the 1940s and are considered the first line of therapy. Most patients will respond to prednisone at a dose of 1 mg/kg for 10 to 14 days followed by a slow taper over 2 to 3 months, depending on the extent of hemolysis. ORRs of up to 90%, with 65% CRs, have been reported with the use of steroids. Unfortunately, approximately 60% of patients relapse when steroid therapy is stopped. Rituximab 375 mg/m^2 weekly for 4 weeks is often effective for steroid-resistant AIHA or ITP and if steroid withdrawal is not possible. Because of the long-term morbidity of prolonged steroid administration in CLL and data demonstrating benefit to concurrent steroids and rituximab for rapid withdrawal of corticosteroids in ITP, our group gives these two concurrently at diagnosis of ITP or AIHA unless contraindicated (e.g., hepatitis B). IVIG, the next line of treatment, induces responses in 40% of patients for both AIHA and ITP. Thrombopoietin agonists are effective for refractory ITP in CLL and could also be considered at this time. Cyclosporin A (CSA) has been used for refractory AIHA and ITP of CLL at 5 mg/kg/day given in divided doses twice daily. The dose should be adjusted to maintain a serum level of around 100 to 150 μg/dL. Other treatment modalities include splenectomy or splenic irradiation, alkylating agents, or therapy (FCR or FR directed at the disease if active). Treatment of the underlying CLL is generally required for long-term control of autoimmune cytopenias. However, our practice is to first control the autoimmune process with steroids or other therapies before considering treatment of the underlying CLL. Supportive therapy with periodic RBC transfusions is also important in the management of AIHA. Ibrutinib has also been shown to reduce the incidence of autoimmune complications in patients who initiate therapy for progressive disease and provides an exciting option for these patients. Unfortunately, it has not been shown to effectively treat active AIHA.

Pure RBC aplasia (PRCA) is a relatively rare T cell–dependent complication associated with CLL, but an incidence as high as 6% has been reported (see Chapter 33). PRCA was first described by Dameshek and colleagues in 1967. It is characterized by a hypoproliferative anemia that can be detected even in early-stage CLL and is thought to be caused by cytotoxic effects of suppressor T cells on erythroid progenitor cells. Higher numbers of these CD3, CD8, and CD57 coexpressing cells have been shown to gradually accumulate in the BM of patients with PRCA. Abeloff and Waterbury described the first remission of PRCA to cyclophosphamide therapy in 1974, and Chikkappa and colleagues described the first case of response to CSA. Subsequent larger studies have shown a response rate as high as 63% with 300 mg/day of oral CSA. Mild reversible nephrotoxicity may warrant dose adjustment in some patients. Most patients exhibit a response by having reticulocytosis within the first 10 to 14 days, but maximal response may occur an average of 10 weeks after the start of therapy. However, steroid therapy at a dose of 1 mg/kg/day of prednisone remains the first line of treatment. If a response is not obtained in 4 weeks, CSA should be added to the regimen. Other agents that have shown promising activity in treating PRCA include rituximab, IVIG, alemtuzumab, and ATG. Packed RBC transfusions are usually indicated in patients who are clinically symptomatic from severe anemia.

A number of other complications, most of which are autoimmune in nature, have been reported in patients with CLL. These complications include paraneoplastic pemphigus, angioedema caused by acquired C1-inhibitor deficiency, and nephrotic syndrome. As a result of autoimmune involvement of various organs, patients with CLL may have abnormal serum chemistry profiles and liver function.

SARS-COV-2 AND CHRONIC LYMPHOCYTIC LEUKEMIA

The pandemic with the SARS-CoV-2 coronavirus that produces COVID-19 syndrome initially was devastating to CLL patients, with a mortality of over 30% (see Chapter 153). Knowledge about early management of infection with Spike protein directed neutralizing antibodies, dexamethasone, and other supportive care have improved outcome since the Spring of 2020. The advent of vaccine-based approaches for SARS-CoV-2 has dramatically reduced cases of COVID-19 in the US and other areas where this treatment approach is available. However, CLL patients have lower response to these vaccines as measured by development of Spike protein directed antibodies and therefore remain susceptible to infection, morbidity, and mortality from COVID-19 syndrome. This poor vaccine response seems to be enhanced by prior therapy with BTKi, CD20 antibodies, and venetoclax, with the latter two treatments almost uniformly predicting absent response to vaccine. Moving forward through the later part of the SARS-CoV-2 pandemic it is likely that this patient population will require other interventions such as neutralizing antibody therapy or enhanced vaccine strategies to prevent COVID-19 syndrome.

FUTURE DIRECTIONS

Advances in the molecular biology of CLL over the past two decades have translated into new diagnostic tests that allow better assessment of initial prognosis and also to assign treatment. Additionally, multiple new therapies have come forward, and progress is being made to extend remission duration, describe resistance mechanisms, develop stopping rules, and improve the quality of life of CLL patients. Additionally, medications and interventions to support complications that arise from CLL have also been introduced. Overall, the future for patients with CLL remains brighter based on these past efforts and likely will improve further with continued laboratory and clinical research ongoing in this disease. In particular, the kinase inhibitors have transformed treatment and outcome of patients with CLL and will continue to alter the natural history of the disease.

CHAPTER 77

HAIRY CELL LEUKEMIA

Farhad Ravandi

Hairy cell leukemia (HCL) is one of the diseases exemplifying the importance of the application of appropriate diagnostic techniques and the importance of treatment strategies to obtain the best treatment outcomes for the individual patient.[1] The disease was first described by Bouroncle and colleagues in 1958. The term *hairy cell leukemia* was first used to describe the disorder by Schreck and Donnelly in 1966 and was derived from the observation of hair-like projections from mononuclear cells, giving rise to a frayed cell surface appearance.

The evolution of therapeutic strategies in patients with HCL over the past 25 years has led to a significant change in the natural history of the disease. Using the currently available drugs, the majority of patients with this disease achieve complete response (CR), and the published survival curves from several large series are similar to those for appropriate age-matched individuals without the disease. At the same time, recent research efforts have led to a better understanding of the molecular mechanisms responsible for the disease pathogenesis. Several studies, using modern techniques, have demonstrated the persistence of minimal residual disease (MRD) after therapy with nucleoside analogs in the majority of patients, without consensus on the significance of such MRD. The role of monoclonal antibodies, naked or conjugated with toxins, in the management of HCL, as well as their ability to eradicate MRD, is under investigation. The possibility of such chemoimmunotherapy strategies, leading to further improvements in the outcome of patients with HCL, needs to be further investigated. More recently, the identification of the *BRAF* V600E mutation present almost universally has led to studies evaluating the role of BRAF-kinase inhibitors in this disease.

EPIDEMIOLOGY

HCL is an uncommon lymphoid malignancy, accounting for only 2% of lymphoid leukemias, with approximately 600 to 800 new patients diagnosed each year in the United States. The disease is more common in white people and occurs more frequently in men than women by a ratio of 4:1. The median age at diagnosis is reported by most studies to be 50 to 59 years. However, it is possible that the disease is underreported in the older population. The Swedish Cancer Registry has maintained records on the incidence of the disease for several decades and has shown a stable incidence since the 1980s. It reports the median age at diagnosis to be 62 years, suggesting less rigid diagnostic efforts in older patients.

HCL has been diagnosed in patients aged in their 20s and 30s but is exceptionally rare in children. Using data from the 17 population-based cancer registry areas in the United States, the National Cancer Institute's Surveillance Epidemiology and End Results program reported that the incidence of the disease was stable in the decades between 1978 and 2004, with a rapid rise in age-specific incidence ratios until approximately age 40 years and then at a slower pace beyond that age.

ETIOLOGY AND CELL OF ORIGIN

Several reports have suggested an association between development of HCL and exposure to benzene, organophosphorus insecticides, and other solvents. However, such association has not been confirmed by other reports. Exposure to radiation, wood dust, or agricultural chemicals, and a previous history of infectious mononucleosis have also been suggested as predisposing factors. However, a direct, causal association has not been established with any of these or other factors.

Morphologically and phenotypically, the cells in HCL have no resemblance to any of the normal stages of B-cell development and maturation; past studies have debated the cell of origin. Initially, because of morphologic and functional similarities between hairy cells and cells of the monocyte/macrophage system, HCL-tumor cells were thought to be derived from a cell transformed from the reticuloendothelium. Prior studies have demonstrated the rearrangement of the B-cell receptor (BCR) immunoglobulin genes in HCL, demonstrating the B-cell origin of the disease. Several studies have increased our understanding of the cell of origin in HCL, allowing for a better description of pathogenic mechanisms responsible for its development.[2]

In lymphoid cells, the analysis of the immunoglobulin variable region genes provides a tool for the delineation of the clonal history of cells at which lymphoid neoplasms originate, identifying whether antigen encountered by a normal mature B cell has resulted in somatic mutation (Fig. 77.1). This process occurs within the germinal centers (GCs) of lymph tissues and may be associated with isotype switching. The enzyme activation–induced cytidine deaminase (AICD) is critical for both processes. Tumor cells from various B-cell malignancies are arrested at a number of stages along normal B-cell differentiation, conserving the immunogenetic characteristics of the stage-specific cell. The analysis of immunoglobulin variable gene regions can provide information about whether the cell of origin has undergone somatic mutation and isotype switching. Several reports have clearly demonstrated that in more than 85% of patients with HCL, the tumor cells express switched immunoglobulin isotypes, and their rearranged variable region genes have undergone somatic mutations.[3] Furthermore, HCL cells express AICD, the enzyme that is critical for both processes.[3] This suggests that the cell of origin in the majority of HCL cases has transited through the GCs of peripheral lymphoid tissue, having undergone the GC reaction.[2] Of interest, in about 40% of cases of HCL, the leukemia cells express multiple immunoglobulin heavy (IGH)-chain isotypes with dominance of immunoglobulin G3 (IgG3) but only a single light chain, suggesting that clonally related, multiple isotypes coexist in single hairy cells. Therefore, this subset of the disease may be arrested at a point after isotype switching and before exit from the GC. However, other lines of evidence suggest a post-GC origin.[2]

Arons and colleagues have provided evidence that in the majority of patients with classic HCL (83% of 102 cases), the cell of origin is post-GC with a mutated IGH-chain variable region.[4] This is contrasted with historic data for patients with chronic lymphocytic leukemia, in which case, about half of the time the cell of origin is un-mutated. They also reported higher usage of certain immunoglobulin-gene families and a difference in mutational frequency among these genes.[4] Furthermore, by demonstrating that the mutations fulfilled predefined characteristics of a canonic and non-random event, Arons and colleagues provided further evidence suggestive of an antigen-driven process.

The post-GC origin of HCL is supported by gene-expression profiling studies, comparing HCL cells with cells from other lymphoid neoplasms and with naïve and memory B cells.[5] HCL patients displayed a homogeneous pattern of gene expression that was clearly

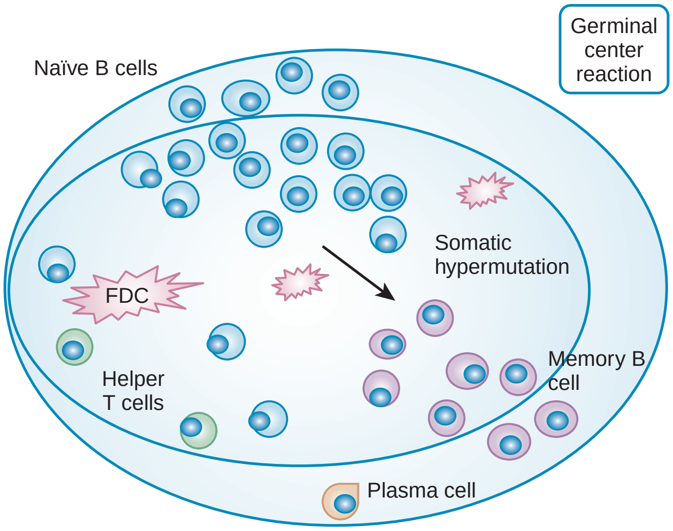

Figure 77.1 GERMINAL CENTER REACTION. The process of somatic hypermutation and isotypic switch in the germinal center. *FDC*, Follicular dendritic cells.

distinct from other B-cell lymphomas and was related to post-GC memory B cells.[5] Other investigators have reported this remarkably stable genome in HCL. Furthermore, when compared with memory B cells, HCL cells had a remarkable conservation of proliferation, apoptosis, and DNA metabolism programs but differed significantly in the expression of genes controlling cell adhesion and response to chemokines.[5] Against the hypothesis of a memory B-cell origin is the lack of expression by hairy cells of the memory B-cell marker, CD27. However, CD27-negative memory B cells have been described in humans, and hairy cells may lose this marker as a result of the neoplastic transformation.

As lymph node involvement in HCL is uncommon, the post-GC cell of origin is likely to originate from the spleen or the bone marrow, which are sites involved by the disease almost invariably. A number of reports have suggested that HCL may originate from the B cells of the splenic marginal zone (SMZ). Normal SMZ B cells are mainly memory B cells. Vanhentenrijk and colleagues, using comparative expressed sequence hybridization studies, demonstrated that hairy cells had an expression profile consistent with a splenic-expression signature that most likely reflected the expression profile of spleen-specific components, such as the sinusoidal-lining cells from the red pulp and the marginal-zone B cells from the white pulp.

Tiacci and colleagues reported the presence of *BRAF* V600E mutations in each of 47 patients with HCL and no mutations in the cells from patients with 195 peripheral B-cell lymphomas or leukemias.[6] Using whole-genome sequencing, in an index patient they identified five missense somatic clonal mutations, including a heterozygous mutation in *BRAF* that resulted in a *BRAF* V600E variant protein.[6] Since *BRAF* V600F is known to be oncogenic in other tumors, Tiacci and colleagues focused on this mutation and analyzed the subsequent 46 cases, as well as the patients with other lymphomas. They also demonstrated expression of phosphorylated MEK and extracellular signal-related kinase (ERK), showing constitutive activation of the RAF-MEK-ERK mitogen-activated, protein kinase pathway in HCL.[6] The presence of the *BRAF* V600E mutation in the hematopoietic stem cells (HSC) in patients with HCL, and the stable engraftment of *BRAF* V600E mutant HSC from a HCL patient into immunodeficient mice that results in a HCL-like disease are further indications of the central role of this mutation to the pathogenesis of HCL.[7] Other studies have further characterized the mutational landscape in HCL, with CDKN1B mutations found in one study to be the second most common mutated gene in HCL.[8]

CLINICAL PRESENTATION AND DIAGNOSIS

Typically, the majority of patients present with pancytopenia and splenomegaly with the associated fatigue, upper-left quadrant abdominal pain, fever, infections, and/or bleeding problems (Table 77.1). Common presenting features include significant anemia seen in up to 85% of patients, thrombocytopenia seen in about 60% to 80%, and leukopenia seen in 60% of patients; these cytopenias can be severe and life-threatening and are likely multifactorial, with hypersplenism and marrow infiltration being the more important contributors. Monocytopenia is a characteristic finding. Circulating hairy cells are typically scant in most patients or frequently absent. Hairy cells are small- and medium-sized lymphoid cells with an oval or indented (bean-shaped) nucleus and with less clumped homogeneous chromatin than in normal B cells (Fig. 77.2). Nucleoli are typically absent or inconspicuous, and the cytoplasm is typically abundant and pale blue in color with circumferential "hairy," projections. Electron micrographs of hairy cells clearly demonstrate their distinctive and complex surface features with multiple surface folds and clusters of short microvilli, creating an appearance unique to hairy cells (Fig. 77.3).

Bone marrow involvement can be interstitial or patchy. The infiltrate is characterized by widely spaced nuclei because of the abundant cytoplasm, giving rise to the commonly described "fried egg," appearance (Fig. 77.4). Occasionally, an increase in the bone marrow reticulin fibrosis, as well as significant loss of the hematopoietic elements, leads to a "dry tap." Bone marrow fibrosis is caused by the production and assembly of a fibronectin matrix by hairy cells and the

deposition of fine reticulin fibers (mainly composed of type III collagen fibrils) by fibroblasts.[2] Hairy cells express isoenzyme 5 of acid phosphatase, which imparts resistance to treatment with tartaric acid, resulting in virtually all cases being positive for tartrate-resistant acid phosphatase (TRAP) (Fig. 77.5). Combined expression of DBA44 and TRAP by immunohistochemical analysis is highly specific and useful for arriving at the diagnosis. More recently, immunostaining for annexin A1 (ANAX1) has been reported to be very specific for HCL.[9] ANAX1 can be used to distinguish HCL from its variant form and from other lymphoid neoplasms, such as splenic marginal zone lymphoma (SMZL).[9] Cyclin D1 (encoded by *CCND1* gene) is frequently expressed, but this is not secondary to translocation involving *CCND1*, unlike mantle cell lymphoma. In a proportion of patients, the bone marrow is hypocellular with the loss of hematopoietic elements, which can result in an erroneous diagnosis of aplastic anemia. Immunostaining for antigens, such as CD20, may be helpful to detect the abnormal B-cell infiltrate, hence prompting more specific stains for HCL.

HCL cells have a characteristic immunophenotype, with flow cytometry being an important element of diagnostic evaluation in this disease (see Table 77.1). Hairy cells strongly express CD45 and gate within the monocytic region when analyzed by CD45 versus side scatter, which is typically devoid of monocytes. They exhibit a mature B-cell phenotype and commonly express one or more heavy chains and monotypic light chains (κ and λ light chains in equal numbers of patients). They express B-cell-associated antigens CD19, CD20, CD22, FMC7, and CD79b but typically lack CD5, CD10 (positive in about 10%), and CD23 (positive in about 20%) expression. No single marker is specific for distinguishing HCL from other B-cell neoplasms; however, the antigens CD11c, CD103, CD123, as well as the interleukin (IL)-2 receptor α-subunit (CD25), are typically expressed in HCL. Bright expression of CD22 and CD20 is also seen, which can be important therapeutically. Among the patients evaluated in one study, CD52 was also universally expressed.

Splenic enlargement is present in the majority of patients and can be massive in about 20% of cases. Splenic involvement is characterized by diffuse infiltration of the red pulp cords and sinuses, with atrophy and replacement of white pulp. Blood-filled sinuses lined by hairy cells (often referred to as *pseudosinuses* or *red blood lakes*) are often a prominent but not a pathognomonic finding (Fig. 77.6). Significant lymphadenopathy is uncommon and present only in the advanced stages of the disease. When involved, the lymph node enlargement is largely confined to the abdominal and retroperitoneal nodes. The infiltrates are distributed in the interfollicular and paracortical areas of the nodes and may extend through the capsule to the surrounding adipose tissue. Hepatomegaly is much less frequent, occurring in up to a third of patients. However, the liver is almost always involved with a mononuclear cell infiltrate in the sinusoids, portal areas, or both. Unusual sites of disease involvement have been reported, including mediastinal and paravertebral masses, skeletal lytic lesions, pleural effusions, and ascites, as well as involvement of the skin, the eye, the central nervous system, and the gastrointestinal tract. Other notable clinical features include a predisposition to infections and an uncommon association with autoimmune disorders, such as polyarteritis nodosa, vasculitis, and rheumatoid arthritis.

Several cytogenetic abnormalities have been reported in HCL, but no single abnormality is present consistently. Few cytogenetic studies have been reported because of the rarity of the disease, difficulty in obtaining marrow samples, and low responsiveness of hairy cells to common mitogens. In the reported series, chromosomes 1, 2, 5, 6, 11, 14, 19, and 20 are most frequently involved, with chromosome 5 and 14 abnormalities predominating. Deletions and mutations of p53, as well as overexpression of cyclin D1, have been reported. Lack of reciprocal, chromosomal translocations in HCL is consistent with a memory B-cell origin of the disease because these

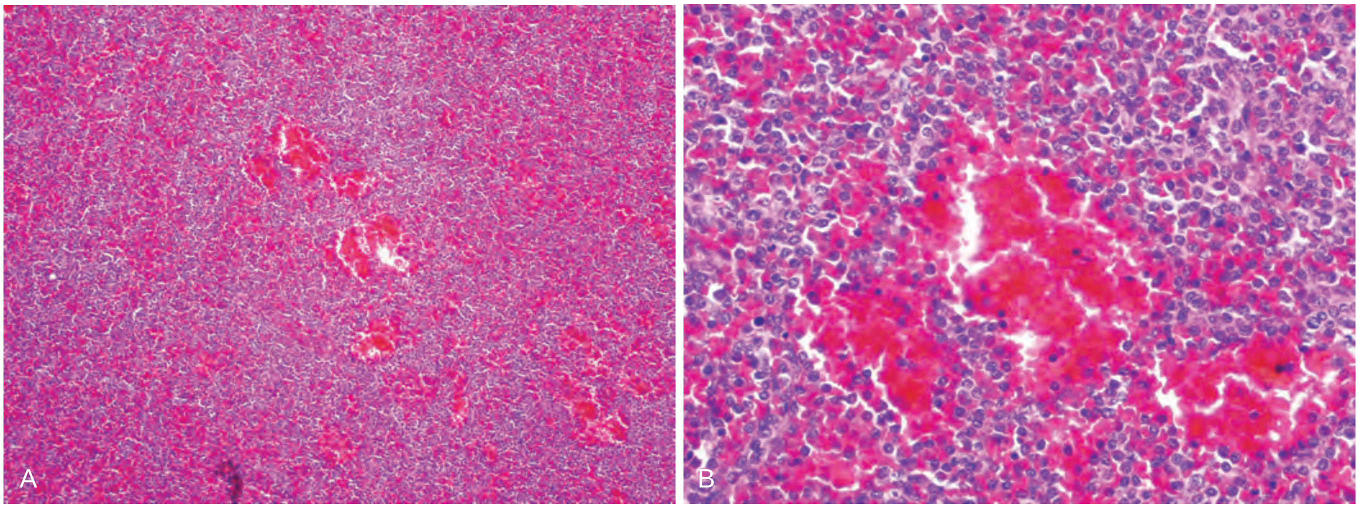

Figure 77.6 PATHOLOGIC FINDINGS IN THE SPLEEN. (A) Hematoxylin and eosin (H&E) stain (×100). (B) H&E stain (×400). *(Provided by Roberto Miranda, Department of Hematopathology, UTMDACC.)*

translocations are thought to arise from mistakes in the immunoglobulin remodeling mechanisms, which are believed to be turned off in memory B cells.[2]

DIFFERENTIAL DIAGNOSIS

HCL must be distinguished from other indolent lymphoid neoplasms, such as B-prolymphocytic leukemia and SMZL, and most notably, from HCLv, the variant form of the disease. HCLv is a rare disorder accounting for approximately 10% of cases and occurring in an older population, with the median age being 71 years.[10] No reports exist of an association with exposure to carcinogens, radiation, or viral infections, and no specific underlying cause has been described. Patients often have an elevated WBC count ($>10 \times 10^9$/L), including atypical hairy cells with prolymphocytic features and lack monocytopenia. Splenomegaly and cytopenias are present in the majority of patients. The patterns of bone marrow and splenic involvement is similar to HCL and is different from prolymphocytic leukemia and SMZL. The immunophenotypic expression of various lymphoid markers is also different in these disorders, with HCLv lacking CD25 expression, further assisting diagnosis (Table 78.2). Another aid in distinguishing HCL from HCLv is CD123 expression, which is positive in the former and negative in the latter. A number of chromosomal abnormalities, including translocations, have been reported in a few cases. Although HCLv has some similarities to HCL, the two conditions differ in a number of features, most notably being HCLv's lack of responsiveness to classic HCL therapies. As such, it is important to distinguish the two and consider them as separate diseases. HCL and HCLv have different IGH-chain gene repertoires and somatic hypermutation patterns.[4] A recent report also suggested that high expression levels of AICD can distinguish HCL from HCLv and from SMZL. However, the same group was unable to find distinct cytogenetic events to distinguish HCL from its variant, using high-resolution genomic profiling. Most recently, *BRAF* V600F mutations have been shown to occur exclusively in HCL samples and not in those from patients with HCLv and SMZL.

SMZL (previously referred to as *splenic lymphoma with villous lymphocytes [SLVL]*) exhibits some of the clinical and morphologic features of HCL but typically has a more prominent peripheral blood involvement, lacks TRAP expression, and has a different immunophenotype, including absence of expression of CD25 and CD103. HCL should be distinguished from other indolent lymphoid neoplasms, such as chronic lymphocytic leukemia, prolymphocytic leukemia, and follicular lymphomas, but this distinction is typically easily made using the characteristic, morphologic, and immunotypic findings of these disorders (see Table 77.2). Other disorders that should be included in the differential diagnosis include aplastic anemia, primary myelofibrosis, and systemic mast cell disorders.

TREATMENT

Indications for Therapy

International consensus guidelines for the diagnosis and management of patients with classical HCL has been recently published.[1] HCL has an indolent course. Some patients survive many years without receiving therapy. Others do not require further therapy despite persistence of residual morphologic evidence of the disease after the initial treatment.[11] Therefore a watch-and-wait strategy may be appropriate in the initial management of patients with limited or no manifestations of the disease. Disease progression that necessitates therapy is commonly evident by the development of progressive cytopenias and their associated complications, such as infections, bleeding, and progressive fatigue. No specific criteria for therapy have been established, but generally treatment is indicated when the patient has significant cytopenias, symptomatic organomegaly, adenopathy, infections, or constitutional symptoms, such as fever, night sweats, or fatigue. Typical blood counts warranting therapy include an absolute neutrophil count less than 1.0×10^9/L, a platelet count less than 100×10^9/L, and/or a hemoglobin less than 12.0 g/dL.

Historic Aspects of Therapy

Progress in the treatment of patients with HCL over the last 25 years has been significant, with survival curves now approaching those of age-matched cohorts without the disease. Before the introduction of interferon (IFN)-α, splenectomy was used effectively to treat patients with HCL. Although splenectomy does not result in morphologic remissions in the bone marrow, the peripheral blood counts are normalized in up to 70% of patients. Progression of disease can be expected in about 45% within 5 years. Furthermore, the procedure is associated with morbidity and mortality. As such, splenectomy is no longer performed in this disease except in rare, selected patients.

The first report of effective treatment of HCL, with IFN-α, described several patients with progressive disease who received daily doses of 3 million units. Three patients achieved CR with the other four having partial responses (PR). The activity of IFN-α in HCL was further confirmed by several large trials reporting CR rates of 4% to 30% and PR rates of 43% to 86%. Even in patients achieving a CR, careful morphologic examination of the bone marrow revealed residual hairy cells. After further follow-up of patients treated with IFN-α, it became clear that a significant proportion would relapse and require further therapy. However, the same authors reported that a number of patients remaining alive after a 10-year follow-up had not required further therapy with interferon. The median failure-free survival reported by these and other investigators ranges from 6 to 25 months. A number of predictors of outcome have been evaluated, with expression of CD5 reported as a predictor of poor response.

The precise mechanism of action of IFN-α in HCL is unknown and may be related to the reduced production of a number of cytokines, such as granulocyte colony-stimulating factor, granulocyte-macrophage colony-stimulating factor, IL-3, and IL-6. Others have demonstrated that IFN-α can mediate apoptosis of hairy cells through the effects of tumor necrosis factor-α.

Treatment with IFN-α is associated with significant toxicity including flu-like symptoms, anorexia, fatigue, nausea, vomiting, diarrhea, skin rash, peripheral neuropathy, and dysfunction of the central nervous system (such as depression and memory loss). These adverse events and the introduction of nucleoside analogs that are generally more effective in achieving responses has led to the use of interferon being limited to rare cases and special circumstances.

Purine Nucleoside Analogs

Although there are no specific guidelines for the treatment of HCL, monotherapy with cladribine or pentostatin is the current established standard. Furthermore, despite the lack of a comparative study, a substantial amount of data suggests that both drugs are equally effective in terms of response rate and durability.[12] The use of nucleoside analogs in treating lymphoid neoplasms can be traced back to the observation that children with the deficiency of the enzyme adenine deaminase (ADA) developed severe combined immunodeficiency. The accumulation of the triphosphorylated form of deoxyadenosine (dependent on the action of the enzyme deoxycytidine kinase [DCK]) is thought to be responsible for the lack of lymphocyte development. Similarly, after treatment with purine nucleoside analogs, the accumulation of deoxyadenosine triphosphate results in DNA strand breaks, inhibition of DNA repair, and apoptosis preferentially in lymphoid cells that are rich in DCK and low in 5′ nucleotidase (the enzyme responsible for degrading deoxyadenosine monophosphate).

Cladribine is a purine nucleoside analog resistant to deamination by ADA. It accumulates in lymphocytes rich in DCK and inhibits ribonucleotide reductase, impairing DNA synthesis and repair. Cladribine has been very effective for the initial therapy of HCL. The overall response rates range from 75% to 100% after a single course of the drug (Table 77.3). Piro and colleagues first reported 12 patients with HCL who received cladribine 0.1 mg/kg per day by intravenous continuous infusion for 7 days.[13] Eleven patients achieved CR, and one had PR.[13] Since then, other doses, routes of administration, and schedules of the drug have been used effectively (see Tables 77.3 and 77.4). In a pilot study, weekly administration was evaluated in severely neutropenic patients in an effort to produce a less toxic strategy.[14] The authors reported a 73% CR rate and an overall response rate of 100%. However, only 16% developed severe neutropenia and only 8% developed infections.[14] In another report, 132 patients with untreated HCL were randomized to receive cladribine either on 5 consecutive days or a novel schedule of six weekly doses.[15] The response rates, overall response rates, progression-free, overall survival, and incidence of grade 3 and 4 infections were the same in the two arms.[15] The subcutaneous route was also evaluated after the initial demonstration that similar plasma levels of those seen with the intravenous route can be achieved subcutaneously. Juliusson and colleagues treated 73 patients with cladribine daily administered as a subcutaneous injection for 7 days and reported a CR rate of 75% after one course and 81% after two courses.[16]

Despite the very high response rate to cladribine, responses are not universal and a significant proportion of patients suffer from relapse. Saven and colleagues reported the long-term outcome of 358 patients with HCL who were followed for a median of 52 months.[17] Of these patients, 26% relapsed after a median of 29 months.[17] The same group reported on 209 patients treated with cladribine with a follow-up period of at least 7 years.[18] Although the overall response rate was 100%, 76 (37%) patients relapsed after their first course of cladribine with a median time to relapse of 42 months.[18] Notably, the time-to-treatment failure curve did not show a plateau, indicating that the treatment is probably not "curative."[18] Outcome of patients achieving CR with their initial therapy is better than those achieving PR (Fig. 77.7). Additional publications have confirmed the high response rate of patients with HCL treated with cladribine and have provided long-term follow-up data.[19] Jehn and colleagues described a 12-year follow-up of 44 patients (including 11 with prior therapy before receiving cladribine) who received cladribine at the originally

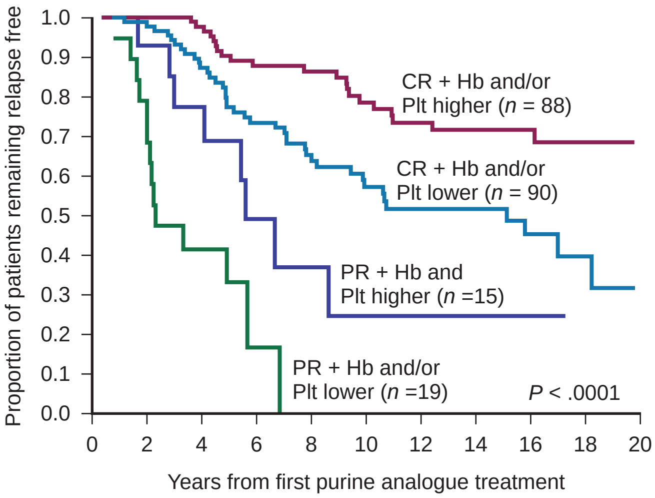

Figure 77.7 LONG-TERM FOLLOW-UP OF PATIENTS TREATED WITH NUCLEOSIDE ANALOG MONOTHERAPY. Excellent outcome for the majority, and significantly better relapse-free survival for patients achieving complete (CR) versus partial response (PR) with initial therapy. *(From Else M, Dearden CE, Matutes E, et al. Long-term follow-up of 233 patients with hairy cell leukaemia, treated initially with pentostatin or cladribine, at a median of 16 years from diagnosis. Br J Haematol. 2009;145:733.)*

reported dose and schedule. The CR rate was 98%, the median follow-up was 8.5 years (range 0.1 to 12.2), and 17 patients had relapsed. Eight of nine patients retreated with cladribine responded again. The overall survival at 12 years was 79%. Zinzani and colleagues reported the long-term outcome of 37 patients treated with one of two regimens of cladribine. Twenty-one patients received cladribine by a 2-hour infusion for 5 days, whereas 16 patients were treated with a once-weekly schedule for 5 weeks. A CR rate of 81% and an overall response rate of 100% was reported, with no difference between the two schedules. After a median follow-up of 122 months (range 54 to 156), the overall relapse rate was about 30% for both groups. The projected overall 13-year and relapse-free survival rates were 96% and 52%, respectively. Investigators at Northwestern University treated 86 consecutive patients with cladribine and reported a CR rate of 79%, as well as a PR rate of 21%.[19] The progression-free survival after 12 years was 54%. After a median follow-up of 9.7 years (range 0.3 to 13.8), 31 patients (36%) relapsed.[19] Of these, 23 were treated with a second course of cladribine, 12 (52%) achieved CR, and 7 (30%) achieved PR. The overall survival after 12 years was 87%. The authors suggested that the lower CR rate in this study was caused by their more stringent criteria for response, which included a requirement for resolution of splenomegaly and lymphadenopathy by computed tomography scan as criteria for CR.[19]

Similar excellent responses have been achieved using pentostatin (Table 77.5). Overall CR rates of 44% to 89% have been reported, with pentostatin administered intravenously at a dose of 2 to 4 mg/m^2 every 2 weeks. Spiers and colleagues were the first to report that a nucleoside analog (pentostatin) was capable of producing CRs in patients with HCL. The activity of pentostatin in HCL was confirmed in a number of larger studies by several investigators. Grever and colleagues conducted a large, randomized clinical trial comparing pentostatin with IFN-α in patients with previously untreated HCL.[20] Patients were randomized to receive either 3 million units of IFN-α subcutaneously three times per week or pentostatin 4 mg/m^2 intravenously every 2 weeks.[20] Patients who did not respond to initial treatment were crossed over. Confirmed complete and overall response rates were reported for 76% and 79% of patients treated with pentostatin, respectively, as compared with 11% and 38% of those treated with IFN-α.[20] Response rates were significantly higher ($P < .0001$), and relapse-free survival was significantly longer with pentostatin than with interferon ($P < .0001$).[20] Furthermore, patients who were initially assigned to receive interferon were frequently crossed over to pentostatin therapy, achieving a CR rate of 66%. In a follow-up report, Flinn and colleagues described the long-term outcome of 241 patients who were treated with pentostatin either as initial therapy or after failure of IFN-α.[21] The 5- and 10-year event-free survival rates were 85% and 67% respectively (Fig. 77.8). Other investigators have reported long-term follow-up data on patients treated with pentostatin. Maloisel and colleagues reported an outcome of 230 evaluable patients with HCL, treated with pentostatin, including 84 with pentostatin as the initial agent. They reported a CR rate of 79%, with an overall response rate of 96%. With a median follow-up of 63.5 months, 34 (15%) of 220 responding patients had relapsed. The estimated 5- and 10-year disease-free survival was 88% and 69%, respectively, and the estimated 5-year overall survival was 89%.

CR, Complete response; *PR*, partial response; *OR*, overall response.

There are no prospective trials comparing the efficacy and durability of response between cladribine and pentostatin. Dearden and colleagues examined the outcome of the patients with the two agents at their institution and reported that 82% of 165 patients treated with pentostatin achieved a CR, compared with 84% of 45 patients treated with cladribine. Relapse rates were 24% with pentostatin and 29% with cladribine, after a median follow-up of 71 and 45 months, respectively. These relapse rates suggest a longer duration of remission with pentostatin. However, with further follow-up, there appears to be no difference between the two agents, with regard to disease-free survival (Fig. 77.9A). Further follow-up data of these cohorts of patients have been reported.[12] With a median follow-up of 16 years, no significant difference existed in the outcome of the patients treated with the two drugs. After relapse or non-response, patients could be successfully retreated with pentostatin or cladribine but achieved lower response rates, with a decline in the proportion of patients achieving CR with second- and third-line therapy (see Fig. 77.9A).[12] However, CRs were equally durable after first, second, or third line of treatment. Complete responders and those with pretreatment hemoglobin greater than 10.0 g/dL and platelet count greater than 100 × 10^9/L, had the longest relapse-free survival ($P < .0001$) (Fig. 77.10).[12] Patients who were in CR after 5 years had only a 25% risk for relapsing by 15 years.[12] These data suggest that both pentostatin and cladribine are highly effective in treating patients with HCL but not curative in all patients. Few predictors of response and long-term outcome have been reported, but the demonstration by two groups that patients with unmutated IGH-chain variable *(IGHV)* region gene were less likely to respond to cladribine suggests that further insight into the biology of the disease may potentially clarify mechanisms of resistance (Fig. 77.11).[22,23]

Monoclonal Antibodies

Several therapeutic options are now available for patients with relapsed HCL. The efficacy of the monoclonal antibody, rituximab, in treating

these patients has been suggested by a number of studies (Table 77.6). Rituximab is a monoclonal antibody directed against the pan–B-cell antigen (CD20), which is heavily expressed on the surface of hairy cells. Nieva and colleagues reported their experience with 4 weekly doses of rituximab in 24 patients with HCL who had failed prior treatment with cladribine. The overall response rate was 26%, with 13% CR and 13% PR. No unusual toxicity was reported. Lauria and colleagues treated 10 patients with relapsed/progressed HCL, with 4 weekly doses of rituximab and reported one CR and four PR (overall response rate of 50%). Hagberg and colleagues treated 11 patients with HCL (including three previously untreated patients) with the same regimen of rituximab for 4 weeks. The response rate was 64%, with six CRs and one PR (including one CR in an untreated patient). The Swiss Group for Clinical Cancer Research reported their study of 4 weekly doses of rituximab in 26 patients with relapsed/progressed HCL, showing an 80% response rate, with 32% achieving CR. Thomas and colleagues used an extended regimen of rituximab (375 mg/m^2 weekly for eight doses) to treat 15 patients with relapsed/refractory HCL and reported a response rate of 80%, including eight (52%) CR, two (13%) CR with residual marrow disease, and two (13%) PR.[24]

Rituximab has been evaluated in a sequential strategy to improve responses in patients with HCL, after treatment with cladribine.[25] With a median follow-up of 60 months, a 100% CR rate in both untreated and relapsed HCL and a 5-year failure-free survival of 95% and 100%, respectively,[26] were reported. Rituximab has also been used concomitantly to treat patients with refractory disease, with reported excellent responses, suggesting a possible synergy. The investigators from the Royal Marsden NHS Trust treated 18 patients with either pentostatin ($n = 12$) or cladribine ($n = 6$) in combination with rituximab, after a median of two (range, 1 to 6) prior treatments and reported a CR rate of 89%. Toxicity with the combination was minimal and with a median follow-up of 36 months, all 16 patients who had achieved CR remained in CR. A randomized phase II study compared concomitant or delayed rituximab in 68 previously untreated patients with HCL. They were randomized to receive cladribine with 8 weekly doses of rituximab started on day 1 or at 6 months if the patients were MRD positive.[27] At 6 months, CR rates were 100% versus 88% in patients receiving concomitant therapy versus cladribine monotherapy. MRD-free CR rates were 97% versus 24%, respectively ($P < .0001$). Rituximab is also being evaluated in combination with BRAF inhibitors.

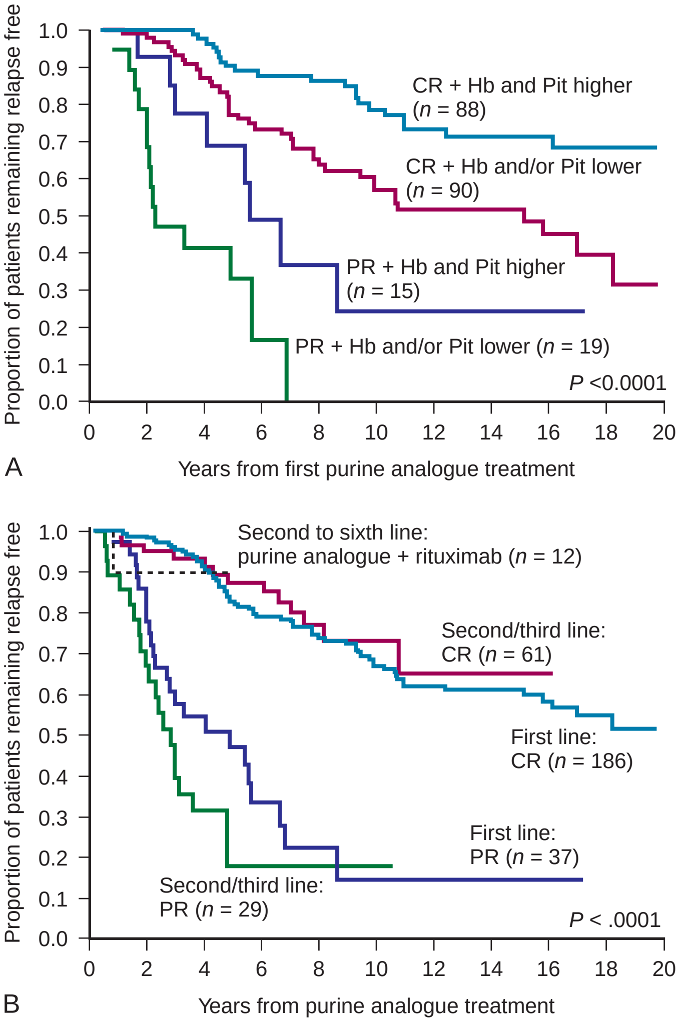

Figure 77.10 (A) Relapse-free survival after initial therapy with nucleoside analogs by initial response and blood counts. (B) Relapse-free survival analyzed by line of therapy and response to treatment. Complete responses (CR) were equally durable, whether achieved at first-, second-, or third-line single-agent treatment. *PR*, Partial response. *(From Else MA, Ruchlemer R, Osuji N, et al. Long remissions in hairy cell leukemia with purine analogs. Cancer. 2005;104:2442; and Else M, Dearden CE, Matutes E, et al. Long-term follow-up of 233 patients with hairy cell leukaemia, treated initially with pentostatin or cladribine, at a median of 16 years from diagnosis. Br J Haematol. 2009;145:733.)*

Other monoclonal antibody–based therapies have developed and are under investigation. BL22 is a recombinant immunotoxin containing the variable domains of the anti-CD22 monoclonal antibody RFB4, fused to a truncated pseudomonas endotoxin A.[28] In a dose-escalation study, 16 patients who were resistant to cladribine were treated with BL22 by intravenous infusion every other day for a total of three doses.[28] Response included 11 CR and 2 PR. The three nonresponders either had preexisting neutralizing antibodies or received low doses of the immunotoxin.[28] Toxicity included a cytokine-release syndrome and development of a reversible hemolytic-uremic syndrome in two patients.[28] In a larger phase I follow-up study of 46 patients with previously treated $CD22^+$ lymphoid malignancies, including 31 with HCL, 61% achieved a CR and 19% experienced a PR, further demonstrating the activity of this agent in HCL. Neutralizing antibodies occurred in 11 (24%) of 46 patients (all HCL), and a reversible hemolytic uremic syndrome, requiring plasmapheresis, was observed in 1 patient with NHL during cycle 1 and in 4 patients with HCL during cycle 2 or 3. The median duration for CR was 36 months (range, 5 to 66 months).

CR, Complete response; *OR*, overall response; *PR*, partial response.

The maximum tolerated dose (MTD) was established at 40 μg/kg every other day × three dose. More recently, the results of a phase II study of the same drug in 36 patients with relapsed or refractory HCL was published.[29] Patients received BL22 at the MTD on cycle 1. Those achieving hematologic remission were observed while the others were retreated at 30 μg/kg every other day for three doses every 4 weeks beginning at least 8 weeks after cycle 1. The response after one cycle (CR, 25%; PR, 25%) improved when 56% were retreated (CR, 47%; PR, 25%).[29] A modified version of this agent, moxetumomab pasudotox (or HA22), is a recombinant immunotoxin targeting C22, fused to a truncated form of pseudomonas exotoxin. This immunotoxin has a superior affinity for CD22 and has been shown to be active in relapsed HCL. A multicenter study in 80 patients with relapsed HCL and two or more prior therapies, showed that moxetumomab pasudotox led to a CR rate of 41% and an objective response rate of 75%. Treatment-related severe adverse events included hemolytic-uremic syndrome (7.5%) and capillary-leak syndrome (5%).[30]

Minimal Residual Disease and Its Significance

Despite excellent responses, there is a definite relapse rate associated with therapy of HCL with both cladribine and pentostatin, and the relapse-free survival does not appear to plateau.[12] Wheaton and colleagues were the first to note that detection of MRD by immunohistochemistry (using anti-CD45RO, anti-CD20, and DBA.44) in paraffin-embedded bone-marrow sections of 39 patients with HCL, in CR, and after receiving cladribine, was predictive of relapse.[27] More sensitive methods of MRD detection, such as immunophenotyping with the use of multiparameter flow cytometry, as well as analysis of antigen-receptor genes by polymerase chain reaction (PCR) with the use of consensus or clone-specific primers, have been evaluated and can be used to monitor the disease course (Fig. 77.12).[25,31,32] Other markers of the disease, such as serum-soluble CD25, CD22, and CD307, have been evaluated and shown to be reliable for disease monitoring.[33]

Rituximab has been evaluated for eradication of MRD assessed by flow cytometry and consensus primer PCR; whether such elimination of MRD can translate to a longer relapse-free survival is unclear.[11,25] Sigal and colleagues reported that patients with HCL may harbor MRD and even other morphologically evident diseases many years after initial therapy, without experiencing overt relapse. This raises the question of whether eradication of MRD should be the goal of therapy in HCL.[11] However, several studies have suggested that patients who achieve a morphologic CR have a better outcome than those with lesser responses. In the study by Chihara et al. the investigators demonstrated that achieving MRD-negative CR after first line, cladribine is greatly enhanced by concurrent rituximab and less so by delayed rituximab. Whether this can be extrapolated to complete eradication of the detectable disease and to create a potential cure remains to be established.[34]

Treatment of Disease Relapse

Despite the success of the nucleoside analogs in achieving generally durable responses in the majority of patients, they are not considered to be curative, with about 40% of patients relapsing by 10 years after treatment.[12] Second and third courses of nucleoside analogs have been used, either with the same or the alternate agent used to treat relapsing disease. However, CRs are less frequent with subsequent courses. Because a single course of cladribine or pentostatin can suppress $CD4^+$ lymphocytes for a substantial period of time, concerns about the use of multiple courses of these agents have been raised.[35]

Rituximab has the advantage of sparing T-lymphocytes and has shown significant activity in patients with relapsed disease (see Table 77.6). However, the overall response rate is relatively low, particularly in studies using only 4 weekly doses of rituximab. Studies of combination therapy with rituximab and nucleoside analogs have reported high response rates, improved activity in variant HCL, and second CR durations longer than the first CR achieved with nucleoside analogs alone.[36,37] Immunotoxins, such as BL22 and HA22, have been studied in cases of relapsed disease, produce high responses, and have limited toxicity; however, they are not, as yet, widely available. Bendamustine, a novel molecule with structural features of both an alkylating agent and a purine nucleoside analog, has been used for the treatment of relapsed and refractory disease. Anecdotal reports have circulated about the use of other agents such as alemtuzumab. BCR signaling kinase inhibitors, such as ibrutinib, have shown significant promise in the treatment of a number of lymphoid neoplasms and are being investigated in patients with relapsed disease and HCLv.[38] A multisite phase II study of ibrutinib in patients with either relapsed classic or variant HCL has been completed.[39] The median duration of follow-up for 37 patients was 3.5 years. The overall response rate at 32 weeks was 24% which increased to 36% at 48 weeks. The estimated 36-month progression-free and overall survival were 73% and 85%, respectively. The most frequent adverse events were diarrhea (59%), fatigue (54%), myalgia (54%), and nausea (51%). Hematologic adverse events were common (anemia [43%], thrombocytopenia [41%], and neutropenia [35%]). The authors concluded that ibrutinib could be safely administered to HCL patients, with objective responses and prolonged disease control in patients that had not responded to frontline therapy.[39]

The identification of *BRAF* V600F as a universal aberration in patients with HCL and the availability of *BRAF* inhibitors for the treatment of solid tumors, such as melanoma, led to the investigation of this agent in patients with relapsed HCL, with promising early reports.[40] The *BRAF* mutation BRAFV600E constitutively activates the mitogen activated kinase pathway in virtually all patients with HCL. Two phase II trials of the BRAF inhibitor, vemurafenib, performed in Italy and the United States, were reported.[41] The treated patients had relapsed or were refractory to treatment with purine analogs. The drug, vemurafenib, was administered orally at a dose of 960 mg orally twice a day for 16 to 18 weeks. The overall response rate was 96% to 100% with a CR rate of 35% to 42%. The progression-free survival rate was 73% and the overall survival was 91%. Myelosuppression was minimal and the most common adverse effects were rash, arthralgia or arthritis.[41] In the United States trial, residual hairy cells in bone marrow, with their associated *BRAF* V600E allele burden, were consistently present at the end of treatment, even after a CR. In approximately half the patients who could be evaluated in the Italian study, these cells showed persistent expression of phosphorylated ERK despite prolonged, ongoing exposure to vemurafenib, which appeared to correlate with a higher burden of residual leukemia and shorter progression-free survival. These findings suggest that leukemic cells develop alternative mechanisms for reactivating MEK and ERK to bypass BRAF blockade retreatment with vemurafenib at the time of relapse was effective in the two trials, although to a lesser extent in the patients who relapsed after a PR than in those who had a relapse after a CR. Tiacci and coworkers have also reported promising results with dabrafenib, which is another oral reversible competitive BRAF inhibitor.[42] The patients participating in these studies had a median of 3.5 prior therapies, including a purine
